Environment Variables

- When run, a program is passed a set of environment variables an array of strings of the form name=value, terminated with NULL.
- access via global variable environ
  - many C implementations also provide as 3rd parameter to main:
    ```c
    int main(int argc, char *argv[], char *env[])
    ```

```c
// print all environment variables
extern char **environ;
for (int i = 0; environ[i] != NULL; i++) {
    printf("%s\n", environ[i]);
}
```

- Recommended you use getenv() and setenv() to access environment variables

getenv() — get an environment variable

```c
#include <stdlib.h>
char *getenv(const char *name);
```

- search environment variable array for name=value
- returns value
- returns NULL if name not in environment variable array

```c
int main(void) {
    // print value of environment variable STATUS
    char *value = getenv("STATUS");
    printf("Environment variable 'STATUS' has value '%s'\n", value);
}
```

```c
source code for get_status.c
```
setenv() — set an environment variable

```c
#include <stdlib.h>

int setenv(const char *name, const char *value, int overwrite);
```

- adds `name=value` to environment variable array
- if `name` in array, value changed if `overwrite` is non-zero

```c
// set environment variable STATUS
setenv("STATUS", "great", 1);
char *getenv_argv[] = "/get_status", NULL);
pid_t pid;
extern char **environ;
if (posix_spawn(&pid, "/get_status", NULL, NULL,
    getenv_argv, environ) != 0) {
perror("spawn");
    exit(1);
}
```

Environment Variables - Why are they useful

- Unix-like shells have simple syntax to set environment variables
  - common to set environment in startup files (e.g. `.profile`)
  - then passed to any programs they run
- Almost all program pass the environment variables they are given to any programs they run
  - perhaps adding/changing the value of specific environment variables
- Provides simple mechanism to pass settings to all programs, e.g
  - timezone (TZ)
  - user’s preferred language (LANG)
  - directories to search for programs (PATH)
  - user’s home directory (HOME)

Example: Changing behaviour with an environment variable

```c
pid_t pid;
char *date_argv[] = { "/bin/date", NULL };
char *date_environment[] = { "TZ=Australia/Perth", NULL };
// print time in Perth
if (posix_spawn(&pid, "/bin/date", NULL, NULL, 
    date_argv, environ) != 0) {
perror("spawn");
    return 1;
}
```

```c
int exit_status;
if (waitpid(pid, &exit_status, 0) == -1) {
perror("waitpid");
    return 1;
}
```

```c
printf("/bin/date exit status was %d\n", exit_status);
```

source code for set_status.c

source code for spawn_environment.c

https://www.cse.unsw.edu.au/~cs1521/23T1/COMP1521-23T1—Processes-5/32
A process is an instance of an executing program.

Each process has an execution state, defined by:

- current values of CPU registers
- current contents of its memory
- information about open files (and other results of system calls)

On Unix/Linux:

- each process had a unique process ID, or PID: a positive integer, type `pid_t`, defined in `<unistd.h>`
- PID 1: `init`, used to boot the system.
- low-numbered processes usually system-related, started at boot
  - ... but PIDs are recycled, so this isn't always true
- some parts of the operating system may appear to run as processes
  - many Unix-like systems use PID 0 for the operating system

Each process has a parent process.

- initially, the process that created it;
- if a process' parent terminates, its parent becomes `init` (PID 1)

Unix provides a range of commands for manipulating processes, e.g.:

- `sh` ... creating processes via object-file name
- `ps` ... showing process information
- `w` ... showing per-user process information
- `top` ... showing high-cpu-usage process information
- `kill` ... sending a signal to a process

On a typical modern operating system...

- multiple processes are active "simultaneously" (multi-tasking)
- operating systems provides a virtual machine to each process:
  - each process executes as if the only process running on the machine
  - e.g. each process has its own address space (N bytes, addressed 0..N-1)

When there are multiple processes running on the machine,

- a process uses the CPU, until it is preempted or exits;
- then, another process uses the CPU, until it too is preempted.
- eventually, the first process will get another run on the CPU.
Multi-tasking

Overall impression: three programs running simultaneously. (In practice, these time divisions are imperceptibly small!)

Preemption — When? How?

What can cause a process to be preempted?

- it ran "long enough", and the OS replaces it by a waiting process
- it needs to wait for input, output, or other some other operation

On preemption...

- the process's entire state is saved
- the new process's state is restored
- this change is called a context switch
- context switches are very expensive!

Which process runs next? The *scheduler answers this. The operating system's process scheduling attempts to:

- fairly sharing the CPU(s) among competing processes,
- minimize response delays (lagginess) for interactive users,
- meet other real-time requirements (e.g. self-driving car),
- minimize number of expensive context switches

Unix/Linux Processes

Environment for processes running on Unix/Linux systems

argv, argc, envp, uid, gid, ...

stdin (fd:0)  Process  stdout (fd:1)
             |                    stderr (fd:2)
             v                    
return status (0 = ok, 10 = error)
Process-related Unix/Linux Functions/System Calls

Process information:
- getpid() ... get process ID
- getppid() ... get parent process ID
- getpgid() ... get process group ID

Creating processes:
- system(), popen() ... create a new process via a shell - convenient but major security risk
- posix_spawn() ... create a new process.
- fork() vfork() ... duplicate current process. (do not use in new code)
- exec() family ... replace current process.

Destroying processes:
- exit() ... terminate current process, see also
  - _exit() ... terminate immediately
    - atexit functions not called,stdio buffers not flushed
- waitpid() ... wait for state change in child process

exec() family - replace yourself

#include <unistd.h>

int execvp(const char *file, char *const argv[]);

- Run another program in place of the current process:
  - file: an executable — either a binary, or script starting with #!
  - argv: arguments to pass to new program
- Most of the current process is re-initialized:
  - e.g. new address space is created - all variables lost
- open file descriptors survive
  - e.g. stdin & stdout remain the same
- PID unchanged
- if successful, exec does not return ... where would it return to?
- on error, returns -1 and sets errno

Example: using exec()

```c
int main(void) {
    char *echo_argv[] = {"/bin/echo", "good-bye", "cruel", "world", NULL};
    execv("/bin/echo", echo_argv);
    // if we get here there has been an error
    perror("execv");
}
```

$ dcc exec.c
$ a.out
good-bye cruel world
$
fork() — clone yourself (OBSOLETE)

```c
#include <sys/types.h>
#include <unistd.h>

pid_t fork(void);
```

Creates new process by duplicating the calling process.
- new process is the child, calling process is the parent

Both child and parent return from fork() call... how do we tell them apart?
- in the child, fork() returns 0
- in the parent, fork() returns the pid of the child
- if the system call failed, fork() returns -1

Child inherits copies of parent's address space, open file descriptors, ...

do not use in new code! use posix_spawn() instead.

fork() appears simple, but is prone to subtle bugs

Example: using fork() (OBSOLETE)

```c
// fork creates 2 identical copies of program
// only return value is different
pid_t pid = fork();
if (pid == -1) {
    perror("fork"); // print why the fork failed
} else if (pid == 0) {
    printf("I am the child because fork() returned %d.\n", pid);
} else {
    printf("I am the parent because fork() returned %d.\n", pid);
}
```

```bash
$ dcc fork.c
$ a.out
I am the parent because fork() returned 2884551.
I am the child because fork() returned 0.
```

waitpid() — wait for a process to change state

```c
#include <sys/types.h>
#include <sys/wait.h>

pid_t waitpid(pid_t pid, int *wstatus, int options);
```

- waitpid pauses current process until process pid changes state
  - where state changes include finishing, stopping, re-starting, ...
- ensures that child resources are released on exit
- special values for pid ...
  - if pid = -1, wait on any child process
  - if pid = 0, wait on any child in process group
  - if pid > 0, wait on specified process

```c
pid_t wait(int *wstatus);
```

- equivalent to waitpid(-1, &status, 0)
- pauses until any child processes terminates.
waitpid() — wait for a process to change state

```c
pid_t waitpid(pid_t pid, int *wstatus, int options);
```

Status is set to hold info about `pid`:
- e.g., exit status if `pid` terminated
- macros allow precise determination of state change
  (e.g. WIFEXITED(status), WCOREDUMP(status))

Options provide variations in `waitpid()` behaviour
- default: wait for child process to terminate
- WNOHANG: return immediately if no child has exited
- WCONTINUED: return if a stopped child has been restarted

For more information, see `man 2 waitpid`.

Example: Using `fork()` and `exec()` to run `/bin/date`

```c
pid_t pid = fork();
if (pid == -1) {
    perror("fork"); // print why fork failed
} else if (pid == 0) {
    // child
    char *date_argv[] = {"/bin/date", "--utc", NULL};
    execv("/bin/date", date_argv);
    perror("execvp"); // print why exec failed
} else {
    // parent
    int exit_status;
    if (waitpid(pid, &exit_status, 0) == -1) {
        perror("waitpid");
        exit(1);
    }
    printf("/bin/date exit status was %d\n", exit_status);
}
```

Example: one of the dangers of `fork` - a fork bomb

```c
#include <stdio.h>
#include <unistd.h>
int main(void) {
    // creates 2 ** 10 = 1024 processes
    // which all print fork bomb then exit
    for (int i = 0; i < 10; i++) {
        fork();
    }
    printf("fork bomb\n");
    return 0;
}
```

Example code for `fork_exec.c`
Example code for `fork_bomb.c`
#include <stdlib.h>

int system(const char *command);

Runs `command` via `/bin/sh`.

Waits for `command` to finish and returns exit status.

Convenient ... but extremely dangerous —
very brittle; highly vulnerable to security exploits

- use for quick debugging and throw-away programs only

```c
// run date --utc to print current UTC
int exit_status = system("/bin/date --utc");
printf("/bin/date exit status was %d\n", exit_status);
return 0;
```

source code for system.c

## posix_spawn() — Run a new process

```c
#include <spawn.h>

int posix_spawn(
pid_t *pid, const char *path,
const posix_spawn_file_actions_t *file_actions,
const posix_spawnattr_t *attrp,
char *const argv[], char *const envp[]);
```

Creates a new process.

- `path`: path to the process to run
- `argv`: arguments to pass to new program
- `envp`: environment to pass to new program
- `pid`: returns process id of new program
- `file_actions`: specifies file actions to be performed before running program
  - can be used to redirect `stdin`, `stdout` to file or pipe
- `attrp`: specifies attributes for new process
  - not used/covered in COMP1521

```c
Example: using posix_spawn() to run /bin/date
```

```c
pid_t pid;
extern char **environ;
char *date_argv[2] = {"/bin/date", "--utc", NULL};
// spawn "/bin/date" as a separate process
if (posix_spawn(&pid, "/bin/date", NULL, NULL, date_argv, environ) != 0) {
    perror("spawn");
    exit(1);
}
// wait for spawned processes to finish
int exit_status;
if (waitpid(pid, &exit_status, 0) == -1) {
    perror("waitpid");
    exit(1);
}
printf("/bin/date exit status was %d\n", exit_status);
```

source code for spawn.c

Example: using posix_spawn() versus system()

```
Running `ls -ld` via system()
```
### getpid(), getppid() — get process IDs

```c
#include <sys/types.h>
#include <unistd.h>

pid_t getpid(void);
pid_t getppid(void);
```

**getpid** returns the process ID of the current process.

**getppid** returns the process ID of the current process’ parent.

---

### Aside: Zombie Processes (advanced)

A process cannot terminate until its parent is notified. - notification is via wait/waitpid or SIGCHLD signal

- **Zombie process** = exiting process waiting for parent to handle notification
  - parent processes which don’t handle notification create long-term zombie processes
    - wastes some operating system resources
  - **Orphan process** = a process whose parent has exited
    - when parent exits, orphan assigned PID 1 (init) as its parent
    - **init** always accepts notifications of child terminations

---

### exit() — terminate yourself

```c
#include <stdlib.h>

void exit(int status);
```

- triggers any functions registered as `atexit()`
- flushes stdio buffers; closes open FILE `*`s
- terminates current process
- a SIGCHLD signal is sent to parent
- returns `status` to parent (via `waitpid()`)
- any child processes are inherited by `init` (pid 1)

```c
void _exit(int status);
```

- terminates current process without triggering functions registered as `atexit()`
- stdio buffers not flushed
**pipe()** — stream bytes between processes

```c
#include <unistd.h>

int pipe(int pipefd[2]);
```

A **pipe** is a unidirectional byte stream provided by the operating system.

- `pipefd[0]`: set to file descriptor of read end of pipe
- `pipefd[1]`: set to file descriptor of write end of pipe
- bytes written to `pipefd[1]` will be read from `pipefd[1]`

Child processes (by default) inherit file descriptors including for pipe

Parent can send/receive bytes (not both) to child via pipe

- parent and child should both close the pipe file descriptor they are not using
  - e.g. if bytes being written (sent) parent to child
    - parent should close read end `pipefd[0]`
    - child should close write end `pipefd[1]`

Pipe file descriptors can be used with stdio via **fdopen**.

---

**popen()** — a convenient but unsafe way to set up pipe

```c
#include <stdio.h>

FILE *popen(const char *command, const char *type);
int pclose(FILE *stream);
```

- runs **command** via `/bin/sh`
- if **type** is "w" pipe to stdin of **command** created
- if **type** is "r" pipe from stdout of **command** created
- **FILE** * stream returned - get then use `fgetc` / `fputc` etc
- **NULL** returned if error
- close stream with **pclose** (not `fclose`)

Convenient, but brittle and highly vulnerable to security exploits ...

use for quick debugging and throw-away programs only

---

**Example: capturing process output with popen()**

```c
#include <stdio.h>

FILE *p = popen("/bin/date --utc", "r");
if (p == NULL) {
    perror("");
    return 1;
}
char line[256];
if (fgets(line, sizeof line, p) == NULL) {
    fprintf(stderr, "no output from date\n");
    return 1;
}
printf("output captured from /bin/date was: '%%s'\n", line);
pclose(p); // returns command exit status
```

source code for `read_popen.c`

---
int main(void) {
    // popen passes command to a shell for evaluation
    // brittle and highly-vulnerable to security exploits
    // popen is suitable for quick debugging and throw-away programs only
    //
    // tr a-z A-Z - passes stdin to stdout converting lower case to upper case
    FILE *p = popen("tr a-z A-Z", "w");
    if (p == NULL) {
        perror("\n");
        return 1;
    }
    fprintf(p, "plz date me\n");
    pclose(p); // returns command exit status
    return 0;
}

Example: sending input to a process with popen()

Example: capturing output from a process:

Example: sending input to a process:

posix_spawn and pipes (advanced topic)

int posix_spawn_file_actions_destroy(
    posix_spawn_file_actions_t *file_actions);
int posix_spawn_file_actions_init(
    posix_spawn_file_actions_t *file_actions);
int posix_spawn_file_actions_addclose(
    posix_spawn_file_actions_t *file_actions, int fildes);
int posix_spawn_file_actions_adddup2(
    posix_spawn_file_actions_t *file_actions, int fildes, int newfildes);

- functions to combine file operations with posix_spawn process creation
- awkward to understand and use — but robust

Example: capturing output from a process:

Example: sending input to a process:
