Slides adapted from those by Kevin Luxa 2521 24T1

divide-and-conquer algorithms  
**split** a problem into two or more subproblems,  
solve the subproblems **recursively**,  
and then **combine** the results.

# Merge Sort

Invented by John von Neumann  
in 1945

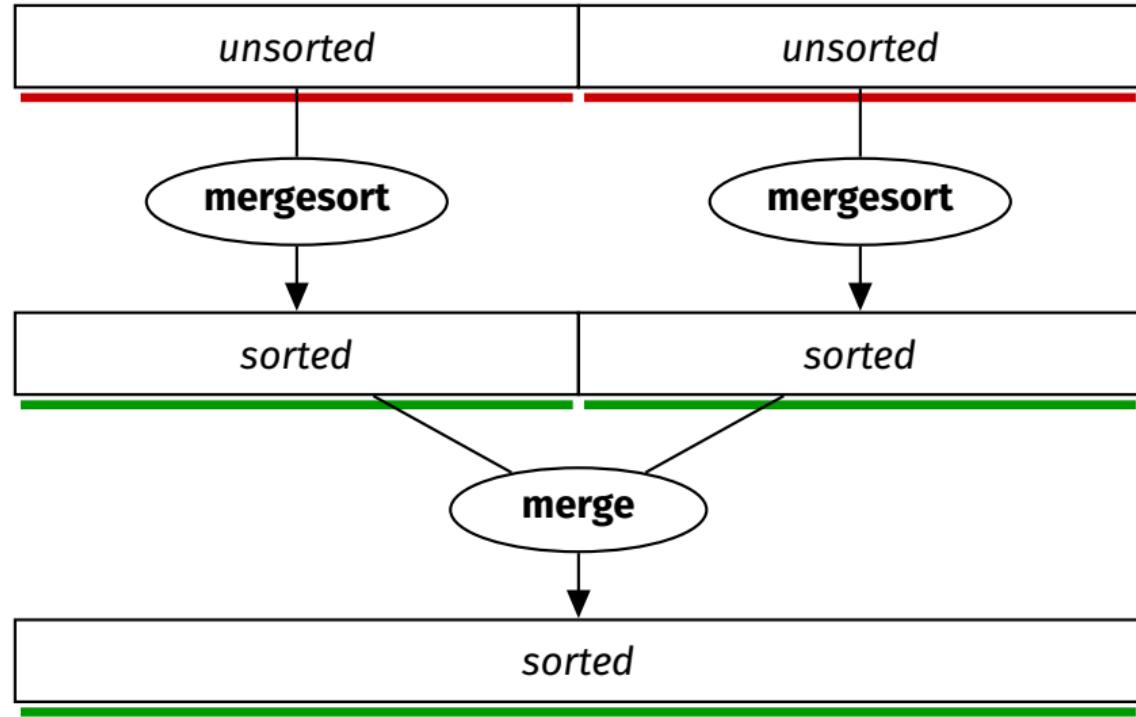

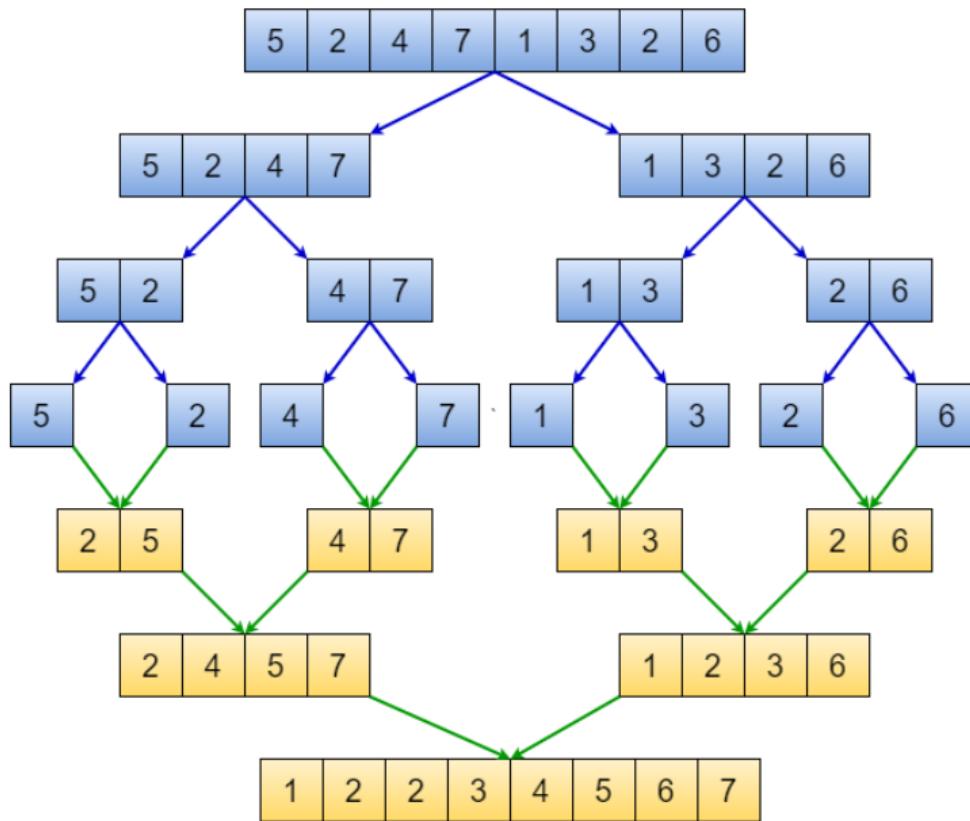

A divide-and-conquer sorting algorithm:

**split** the array into two roughly equal-sized parts

**recursively** sort each of the partitions

**merge** the two now-sorted partitions into a sorted array

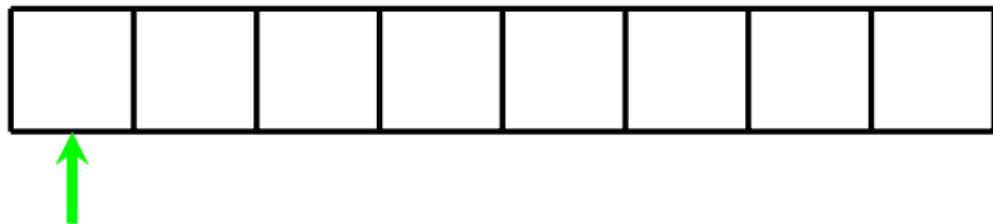

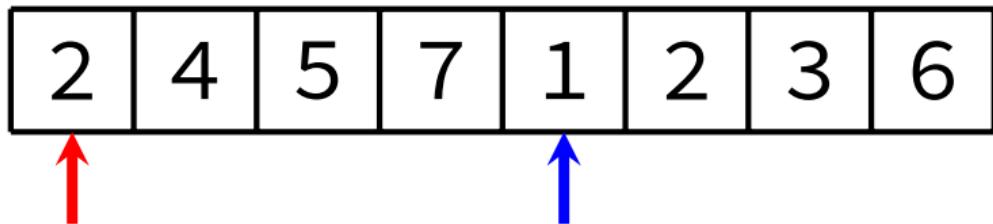

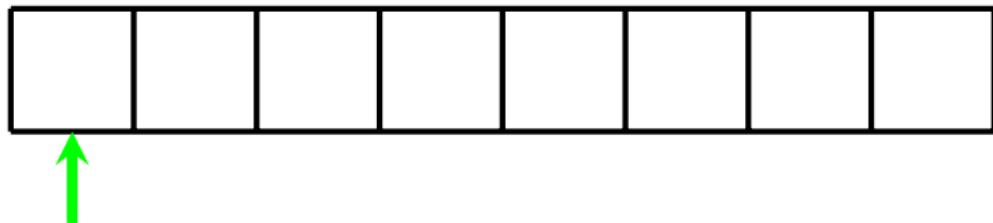

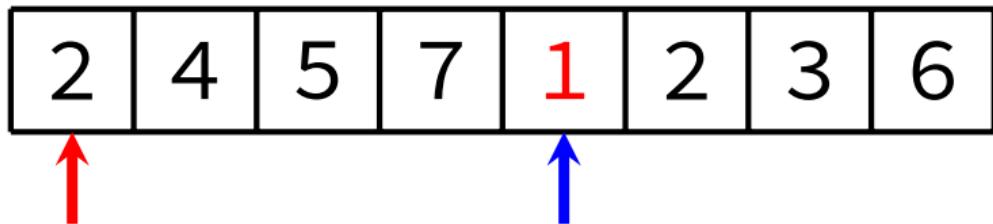

## How do we split the array?

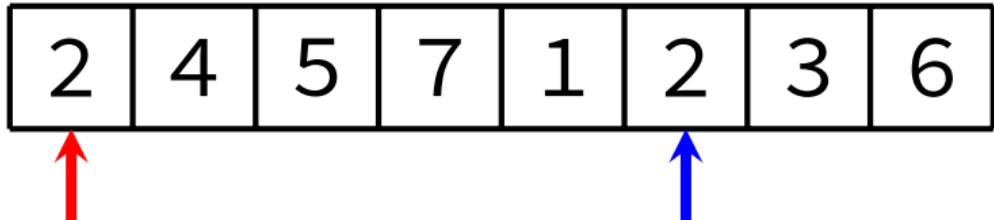

- We don't physically split the array
- We simply calculate the midpoint of the array
  - $\text{mid} = (\text{lo} + \text{hi}) / 2$
- Then recursively sort each half by passing in appropriate indices
  - Sort between indices  $\text{lo}$  and  $\text{mid}$
  - Sort between indices  $\text{mid} + 1$  and  $\text{hi}$
- This means the time complexity of splitting the array is  $O(1)$

How do we merge two sorted subarrays?

- We merge the subarrays into a *temporary array*
- Keep track of the smallest element that has not been merged in each subarray
- Copy the smaller of the two elements into the temporary array
  - If the elements are equal, take from the left subarray
- Repeat until all elements have been merged
- Then copy from the temporary array back to the original array

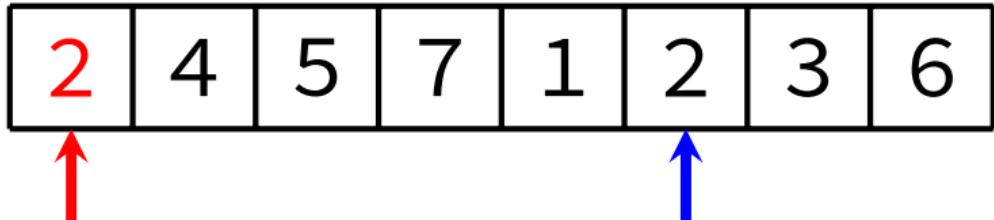

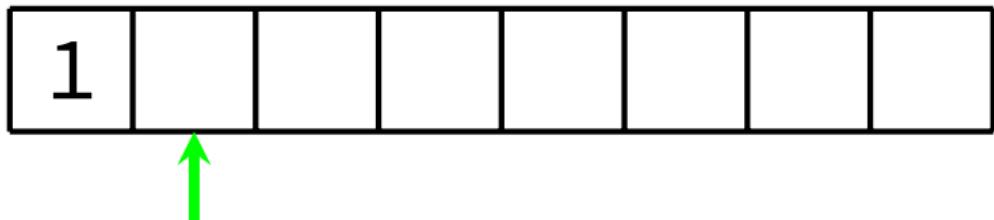

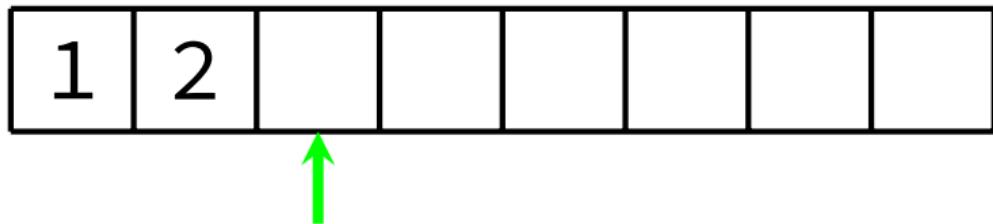

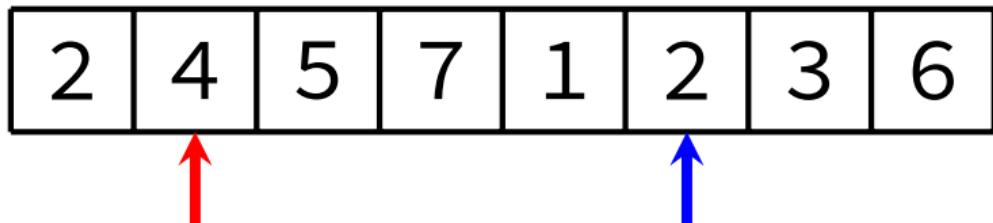

When items are equal, merge takes from the left subarray  
(this ensures stability)

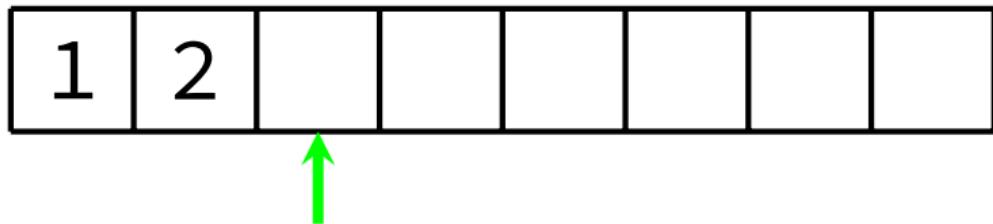

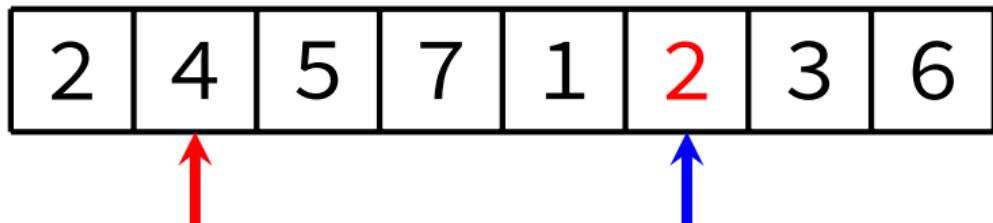

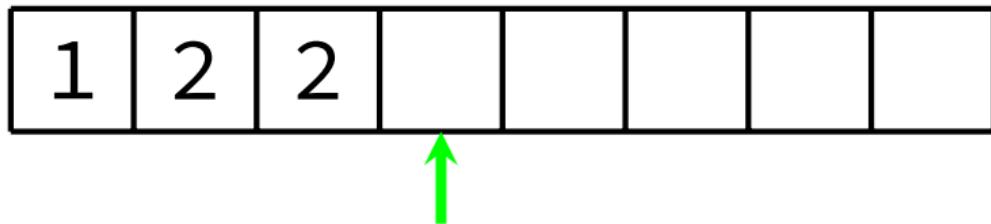

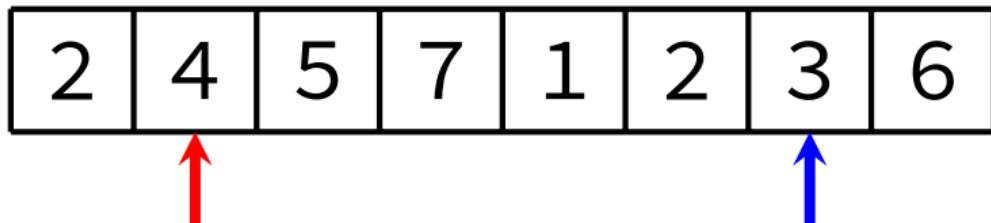

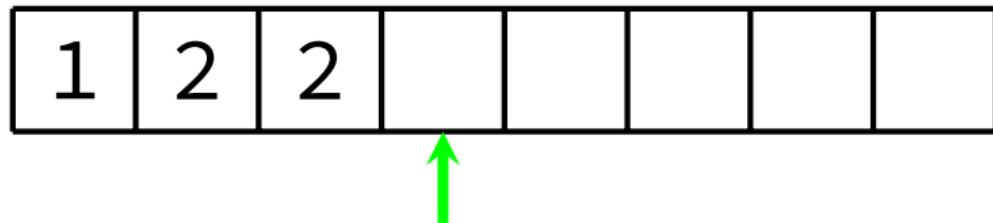

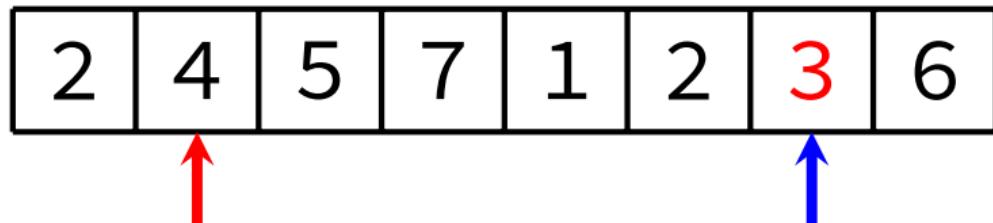

When items are equal, merge takes from the left subarray  
(this ensures stability)

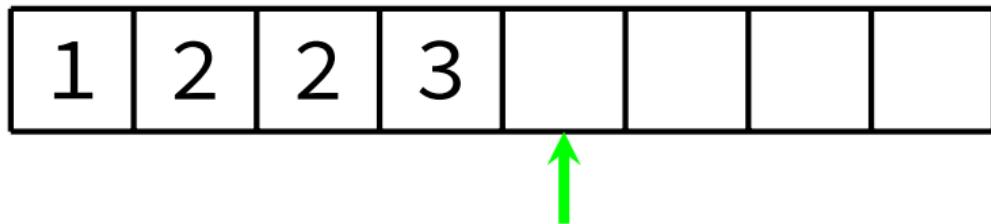

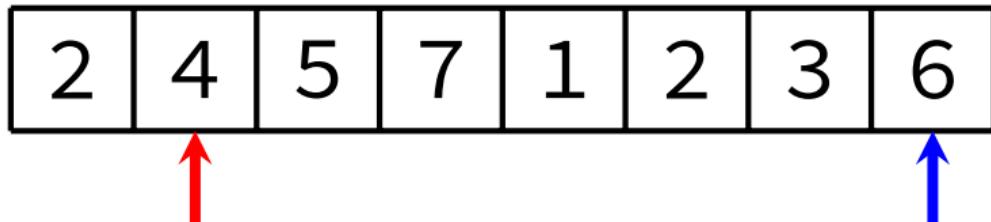

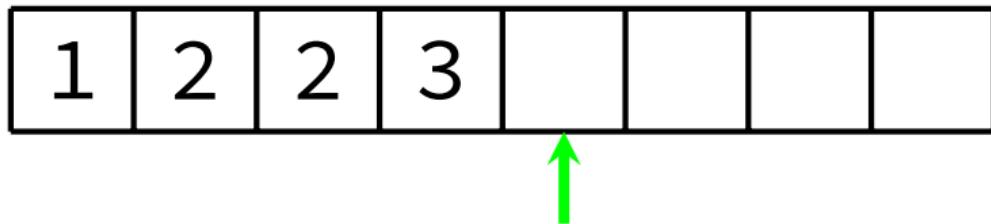

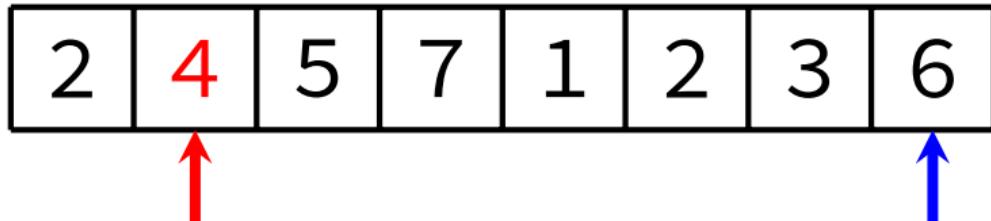

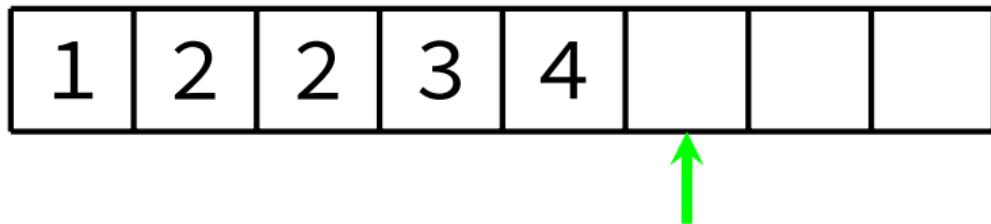

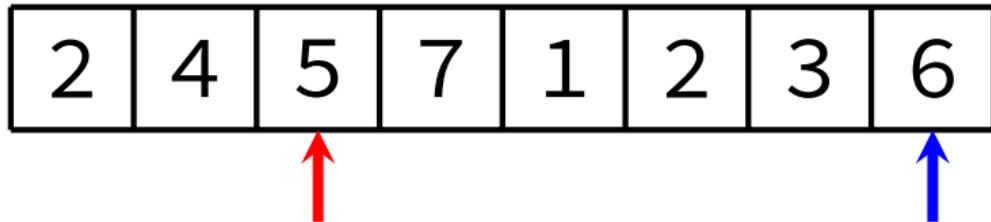

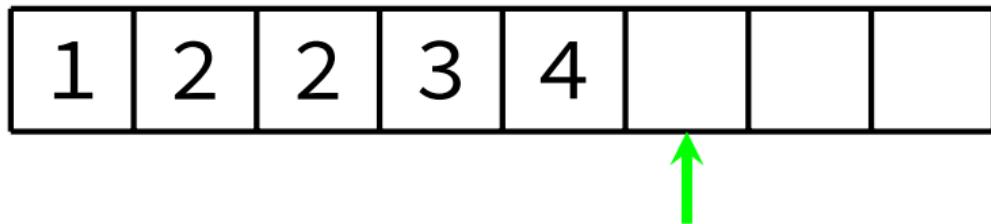

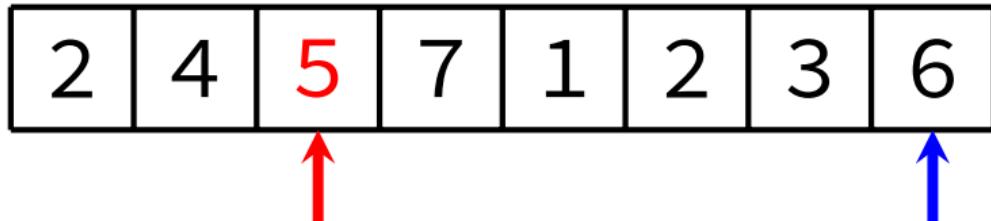

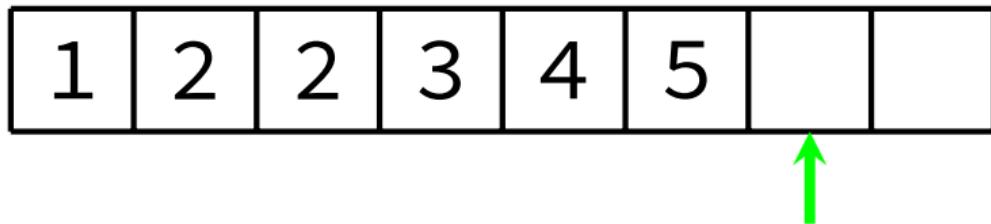

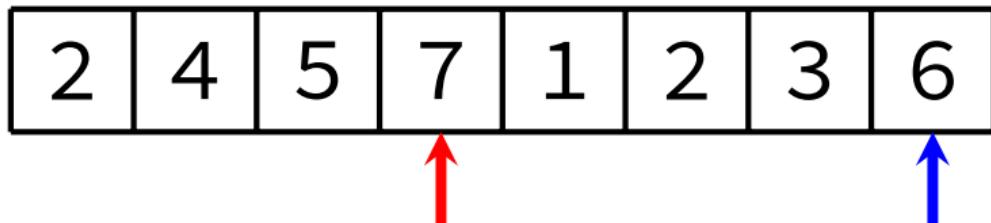

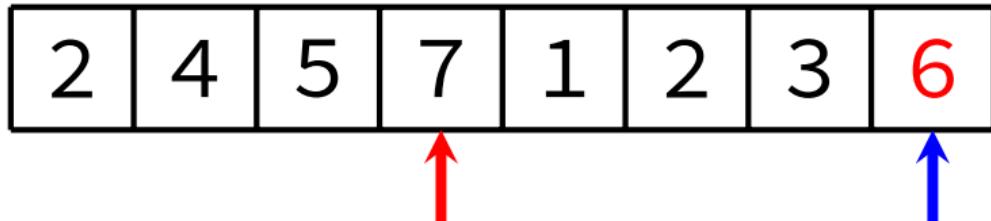

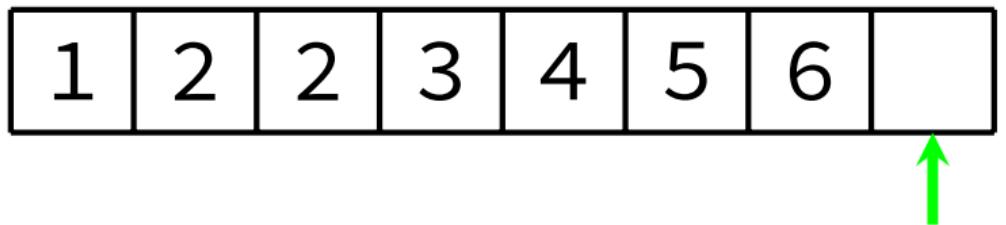

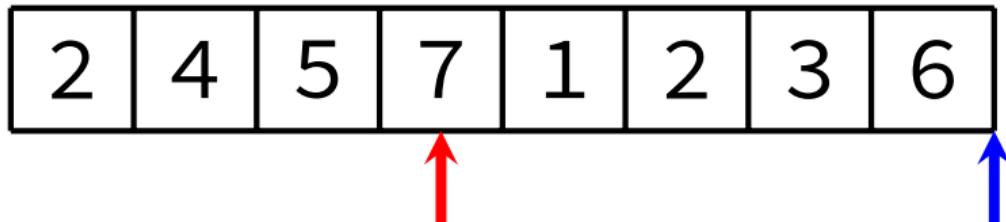

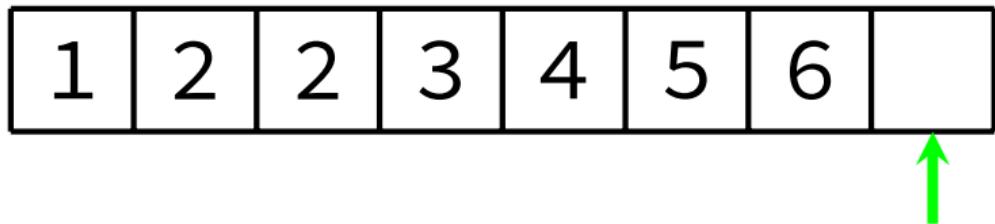

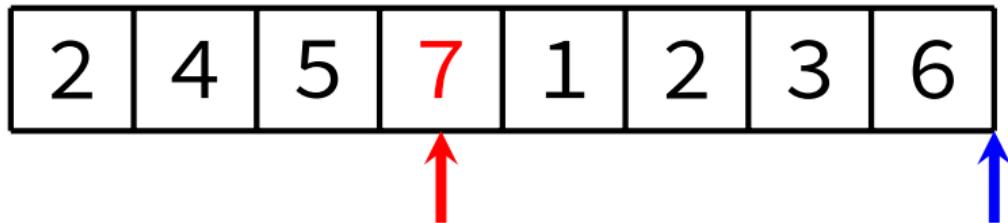

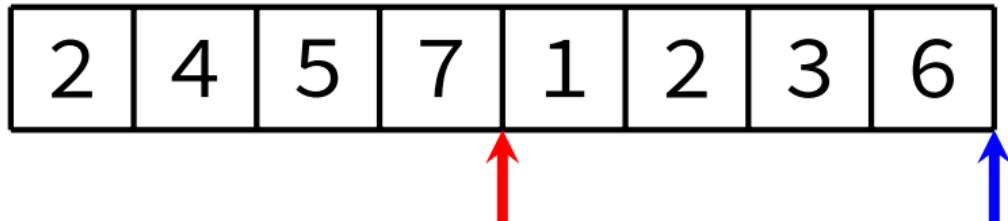

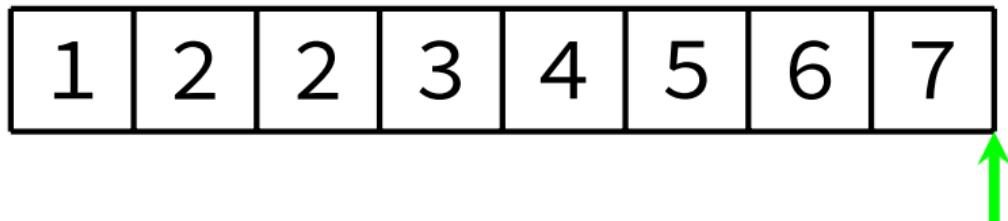

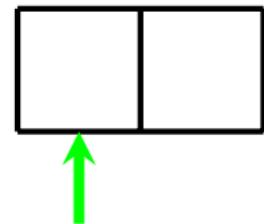

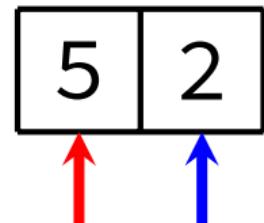

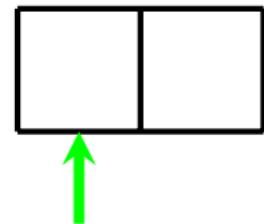

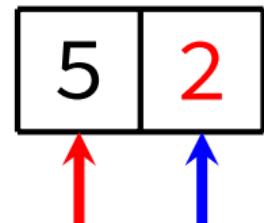

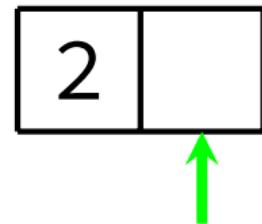

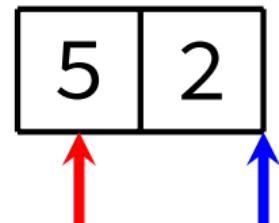

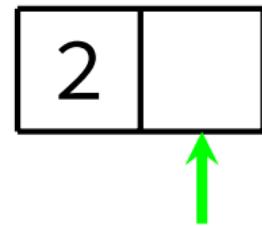

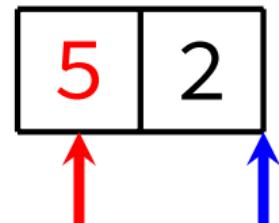

Now copy back to original array

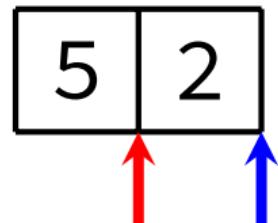

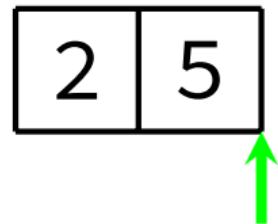

Now copy back to original array

- The time complexity of merging two sorted subarrays is  $O(n)$ , where  $n$  is the total number of elements in both subarrays
- Therefore:
  - Merging two subarrays of size 1 takes 2 “steps”
  - Merging two subarrays of size 2 takes 4 “steps”
  - Merging two subarrays of size 4 takes 8 “steps”
  - ...

```
void mergeSort(Item items[], int lo, int hi) {  
    if (lo >= hi) return;  
    int mid = (lo + hi) / 2;  
    mergeSort(items, lo, mid);  
    mergeSort(items, mid + 1, hi);  
    merge(items, lo, mid, hi);  
}
```

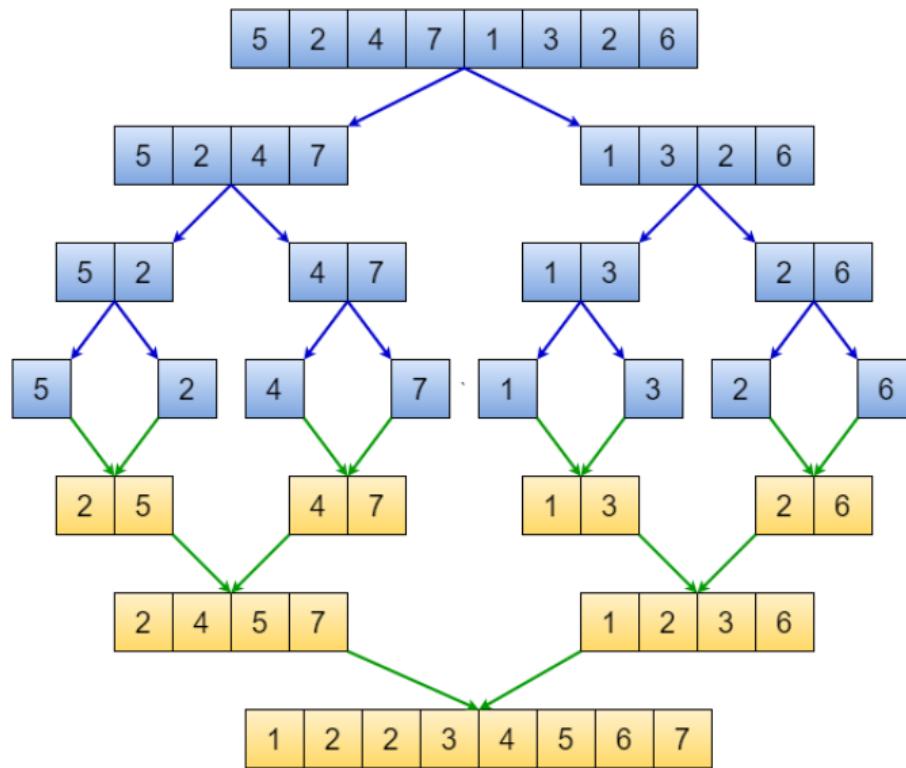

```
void merge(Item items[], int lo, int mid, int hi) {
    Item *tmp = malloc((hi - lo + 1) * sizeof(Item));
    int i = lo, j = mid + 1, k = 0;

    // Scan both segments, copying to `tmp'.
    while (i <= mid && j <= hi) {
        if (le(items[i], items[j])) {
            tmp[k++] = items[i++];
        } else {
            tmp[k++] = items[j++];
        }
    }

    // Copy items from unfinished segment.
    while (i <= mid) tmp[k++] = items[i++];
    while (j <= hi) tmp[k++] = items[j++];

    // Copy `tmp' back to main array.
    for (i = lo, k = 0; i <= hi; i++, k++) {
        items[i] = tmp[k];
    }

    free(tmp);
}
```

**Split**  
 $n - 1$  splits  
( $\log_2 n$  levels  
of splitting)

**Merge**  
We have to merge  
 $n$  numbers exactly  
 $\log_2 n$  times

 $O(n)$  $O(n \log n)$

Analysis:

- Merge sort splits the array into equal-sized partitions halving at each level  $\Rightarrow \log_2 n$  levels
- The same operations happen at every recursive level
- Each ‘level’ requires  $\leq n$  comparisons

Therefore:

- The time complexity of merge sort is  $O(n \log n)$ 
  - Best-case, average-case, and worst-case time complexities are all the same

Note: Not required knowledge in COMP2521!

Let  $T(n)$  be the time taken to sort  $n$  elements.

Splitting arrays into two halves takes constant time.  
Merging two sorted arrays takes  $n$  steps.

So we have that:

$$T(n) = 2T(n/2) + n$$

Then the Master Theorem (see COMP3121) can be used to show that the time complexity is  $O(n \log n)$ .

**Stable**

Due to taking from left subarray if items are equal during merge

**Non-adaptive**

$O(n \log n)$  best case, average case, worst case

**Not in-place**

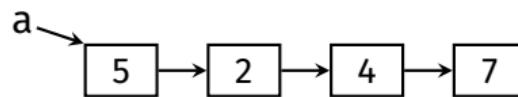

Merge uses a temporary array of size up to  $n$

Note: Merge sort also uses  $O(\log n)$  stack space

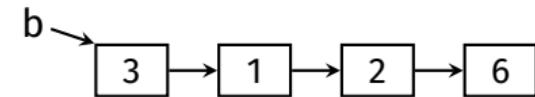

It is possible to apply merge sort on linked lists.

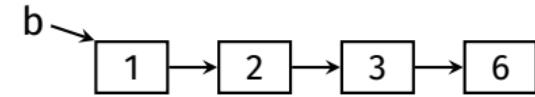

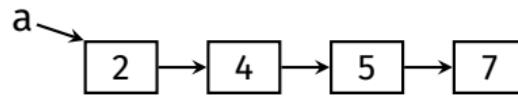

split

mergesort(a)

mergesort(b)

merge(a, b)

An approach that works non-recursively!

- On each pass, our array contains sorted *runs* of length  $m$ .
- Initially,  $n$  sorted runs of length 1.
- The first pass merges adjacent elements into runs of length 2.
- The second pass merges adjacent elements into runs of length 4.
- Continue until we have a single sorted run of length  $n$ .

Can be used for *external* sorting;  
e.g., sorting disk-file contents

	[0]	[1]	[2]	.....	[15]											
Original	A	S	O	R	T	I	N	G	E	X	E	M	P	L	A	R

After 1st pass  
sorted slices of length 2

A	S	O	R	I	T	G	N	E	X	E	M	L	P	A	R
---	---	---	---	---	---	---	---	---	---	---	---	---	---	---	---

After 2nd pass  
sorted slices of length 4

A	O	R	S	G	I	N	T	E	E	M	X	A	L	P	R
---	---	---	---	---	---	---	---	---	---	---	---	---	---	---	---

After 3rd pass  
sorted slices of length 8

A	G	I	N	O	R	S	T	A	E	E	L	M	P	R	X
---	---	---	---	---	---	---	---	---	---	---	---	---	---	---	---

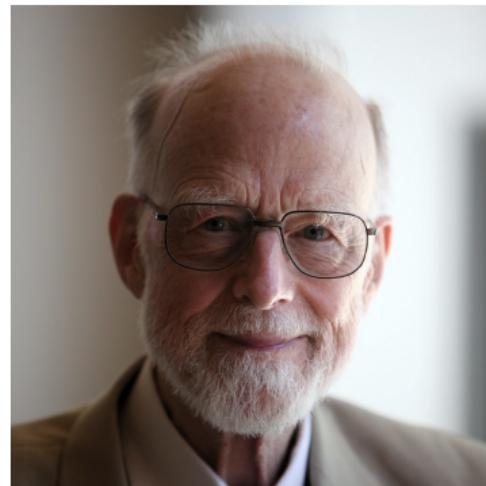

After 4th pass  
sorted slice of length 16

A	A	E	E	G	I	L	M	N	O	P	R	R	S	T	X
---	---	---	---	---	---	---	---	---	---	---	---	---	---	---	---

```
void mergeSortBottomUp(Item items[], int lo, int hi) {  
    for (int m = 1; m <= hi - lo; m *= 2) {  
        for (int i = lo; i <= hi - m; i += 2 * m) {  
            int end = min(i + 2 * m - 1, hi);  
            merge(items, i, i + m - 1, end);  
        }  
    }  
}
```

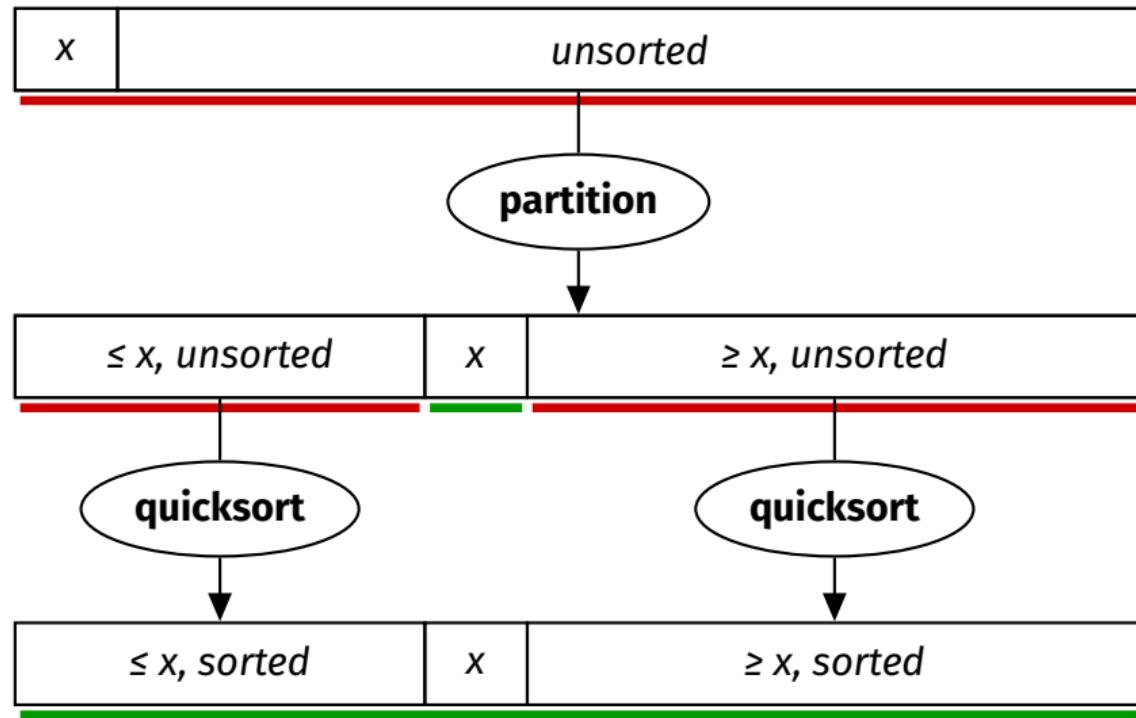

# Quick Sort

Invented by Tony Hoare  
in 1959

### Method:

- ① Choose an item to be a pivot
- ② Rearrange (partition) the array so that
  - All elements to the left of the pivot are less than (or equal to) the pivot
  - All elements to the right of the pivot are greater than (or equal to) the pivot
- ③ Recursively sort each of the partitions

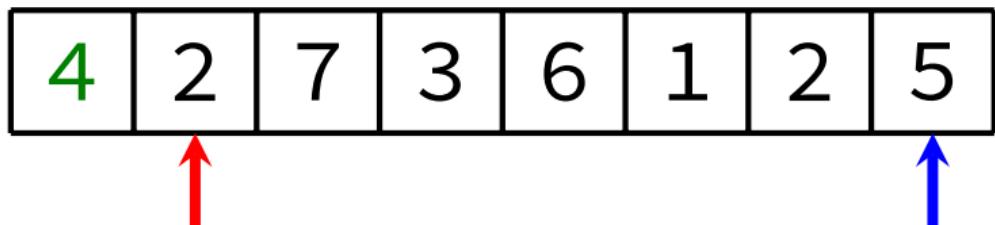

## How to partition an array?

- Assume the pivot is stored at index  $lo$
- Create index  $l$  to start of array ( $lo + 1$ )
- Create index  $r$  to end of array ( $hi$ )
- Until  $l$  and  $r$  meet:
  - Increment  $l$  until  $a[l]$  is greater than pivot
  - Decrement  $r$  until  $a[r]$  is less than pivot
  - Swap items at indices  $l$  and  $r$
- Swap the pivot with index  $l$  or  $l - 1$  (depending on the item at index  $l$ )

Pivot is 4

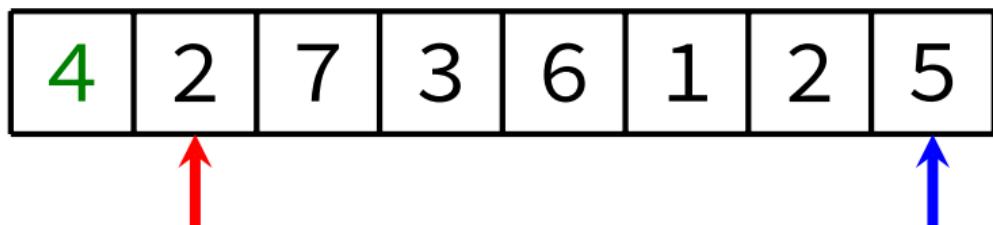

4	2	7	3	6	1	2	5
---	---	---	---	---	---	---	---

Create left and right indices

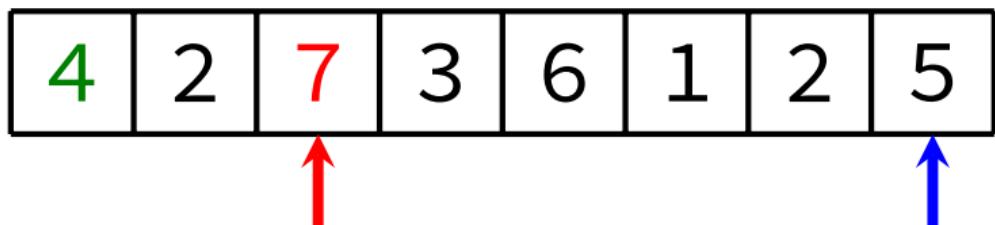

Until the indices meet:

Increment left index while element is  $\leq$  pivot

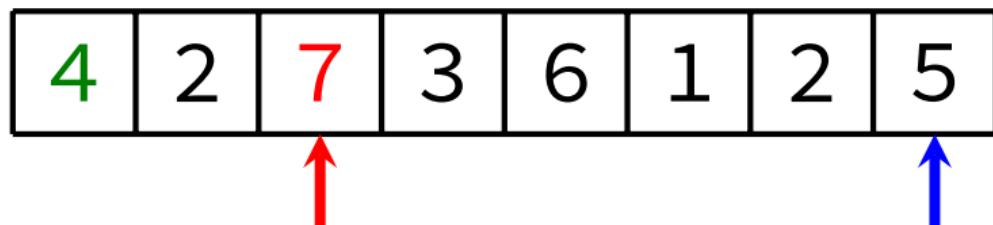

Until the indices meet:

Increment left index while element is  $\leq$  pivot

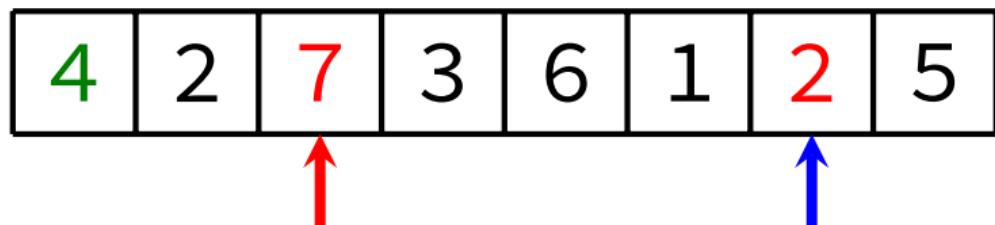

Until the indices meet:

Decrement right index while element is  $\geq$  pivot

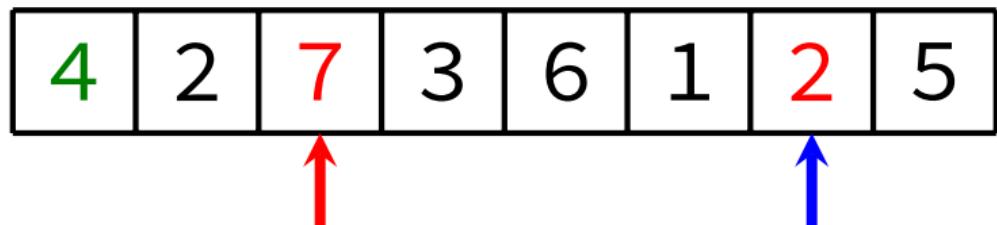

Until the indices meet:

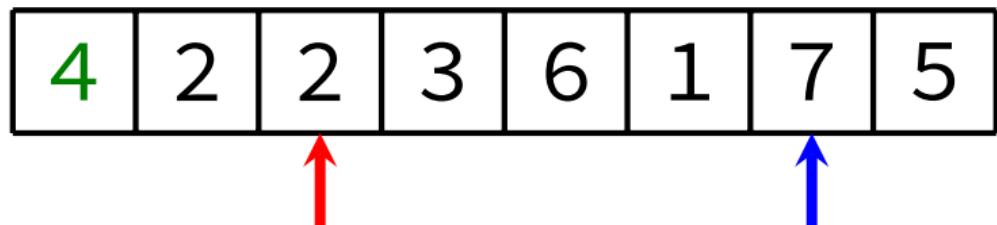

Decrement right index while element is  $\geq$  pivot

Until the indices meet:  
Swap the two elements

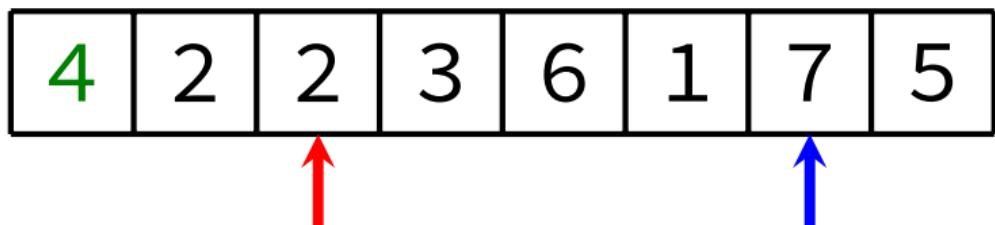

Until the indices meet:  
Swap the two elements

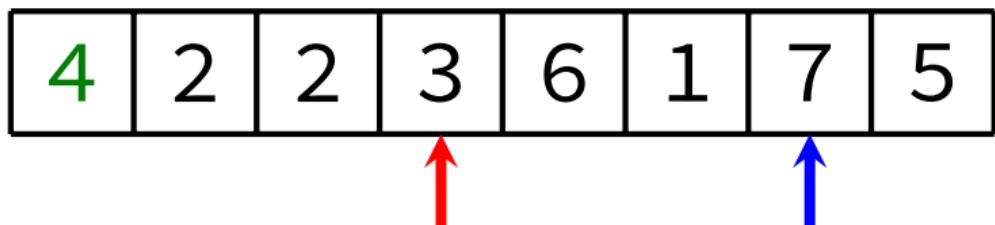

Until the indices meet:

Increment left index while element is  $\leq$  pivot

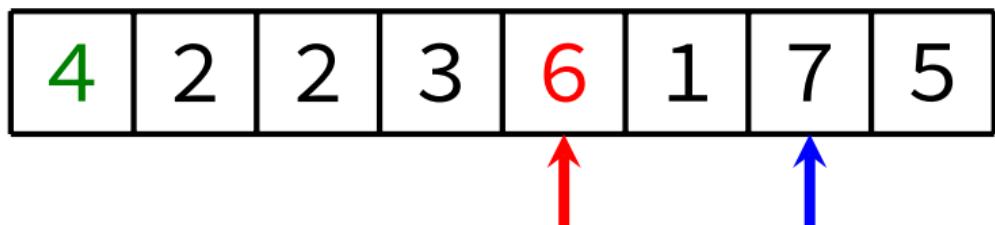

Until the indices meet:

Increment left index while element is  $\leq$  pivot

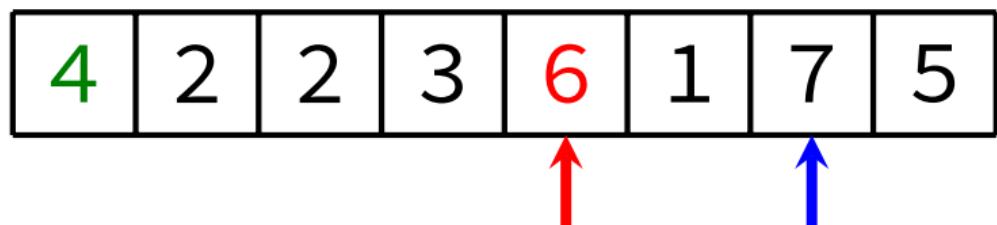

Until the indices meet:

Increment left index while element is  $\leq$  pivot

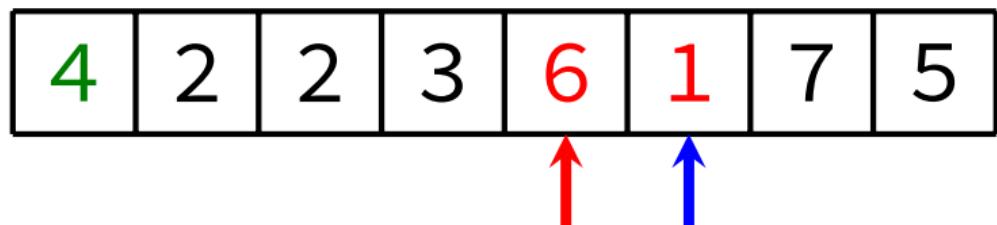

Until the indices meet:

Decrement right index while element is  $\geq$  pivot

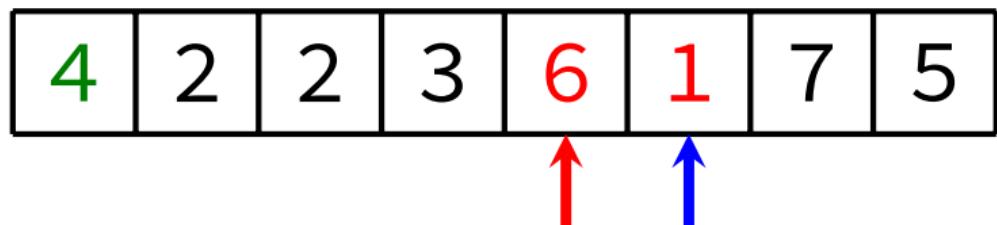

Until the indices meet:

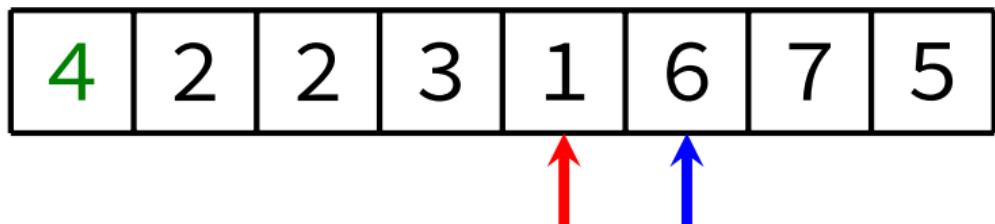

Decrement right index while element is  $\geq$  pivot

Until the indices meet:  
Swap the two elements

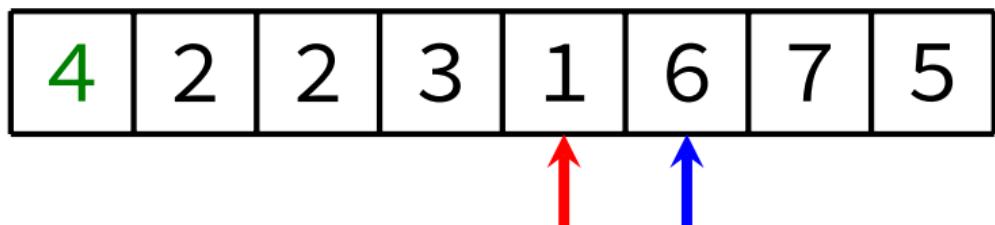

Until the indices meet:  
Swap the two elements

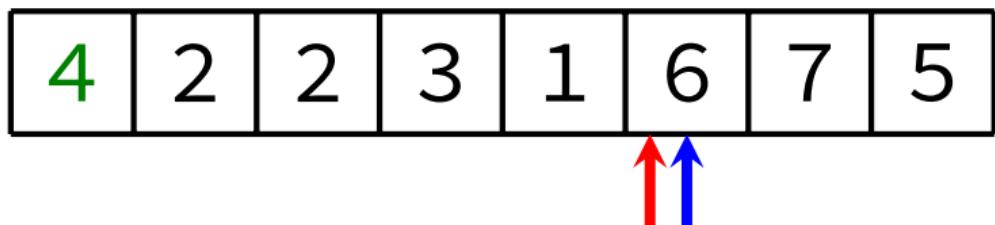

Until the indices meet:

Increment left index while element is  $\leq$  pivot

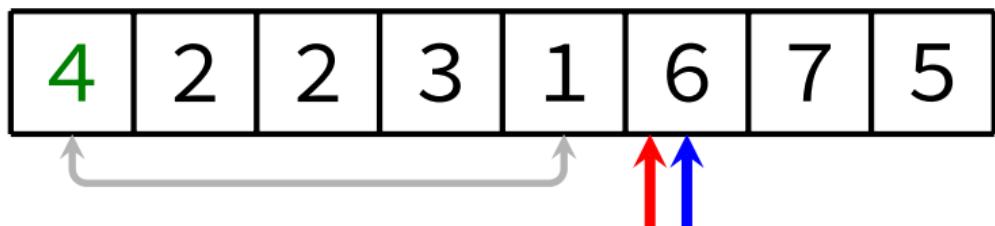

Until the indices meet:

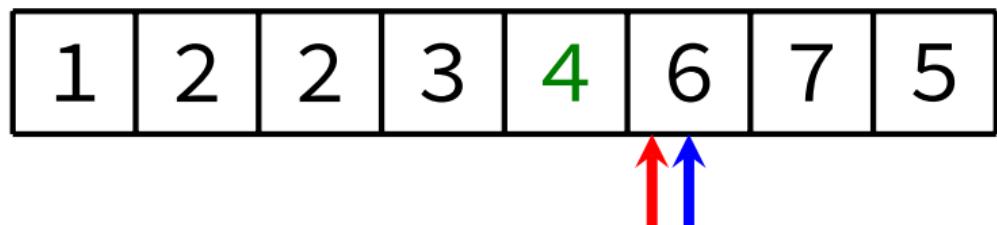

Increment left index while element is  $\leq$  pivot

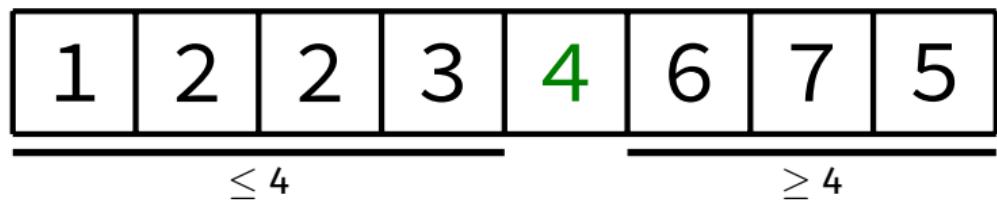

Swap the pivot into the middle (be careful!)

Swap the pivot into the middle (be careful!)

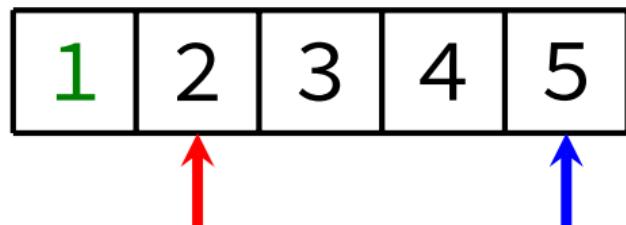

Done

Pivot is 1

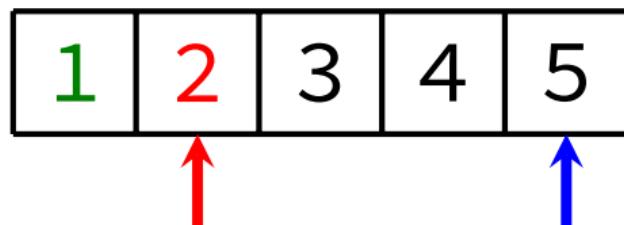

1	2	3	4	5
---	---	---	---	---

Create left and right indices

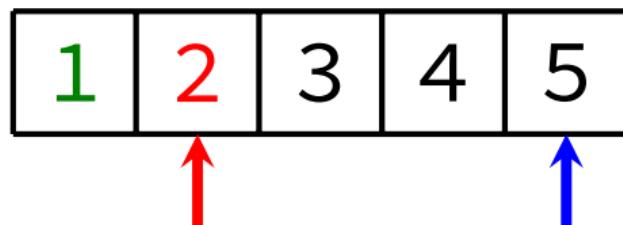

Until the indices meet:

Increment left index while element is  $\leq$  pivot

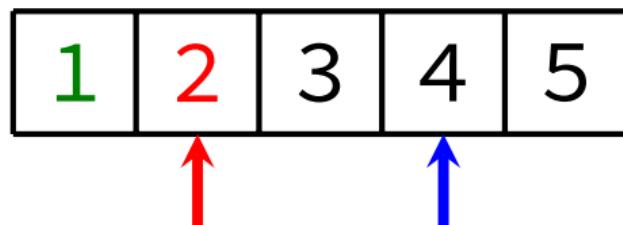

Until the indices meet:

Decrement right index while element is  $\geq$  pivot

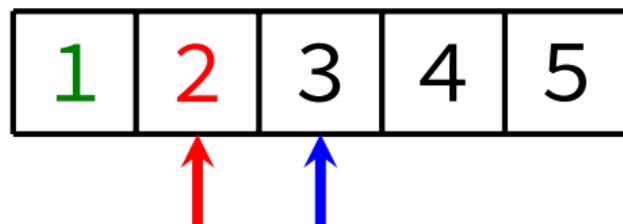

Until the indices meet:

Decrement right index while element is  $\geq$  pivot

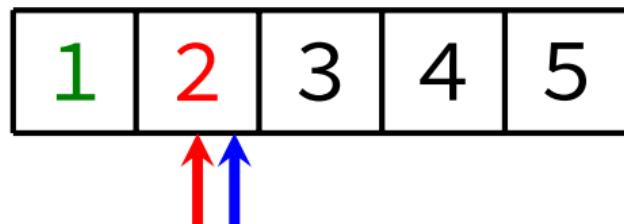

Until the indices meet:

Decrement right index while element is  $\geq$  pivot

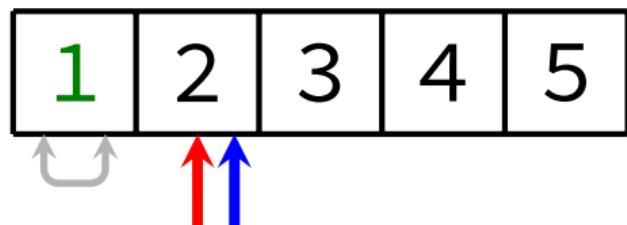

Until the indices meet:

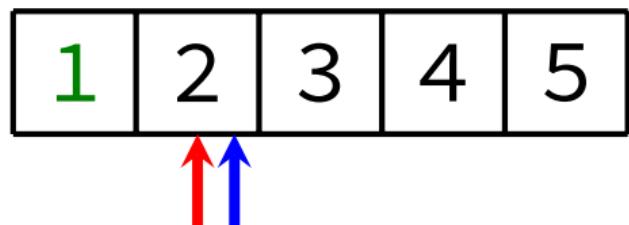

Decrement right index while element is  $\geq$  pivot

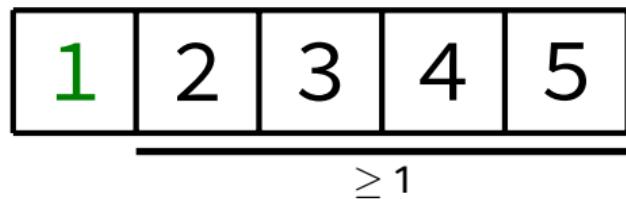

Swap the pivot into the middle (be careful!)

Swap the pivot into the middle (be careful!)

Done

- Partitioning is  $O(n)$ , where  $n$  is the number of elements being partitioned
  - About  $n$  comparisons are performed, at most  $\frac{n}{2}$  swaps are performed

```
void naiveQuickSort(Item items[], int lo, int hi) {  
    if (lo >= hi) return;  
    int pivotIndex = partition(items, lo, hi);  
    naiveQuickSort(items, lo, pivotIndex - 1);  
    naiveQuickSort(items, pivotIndex + 1, hi);  
}
```

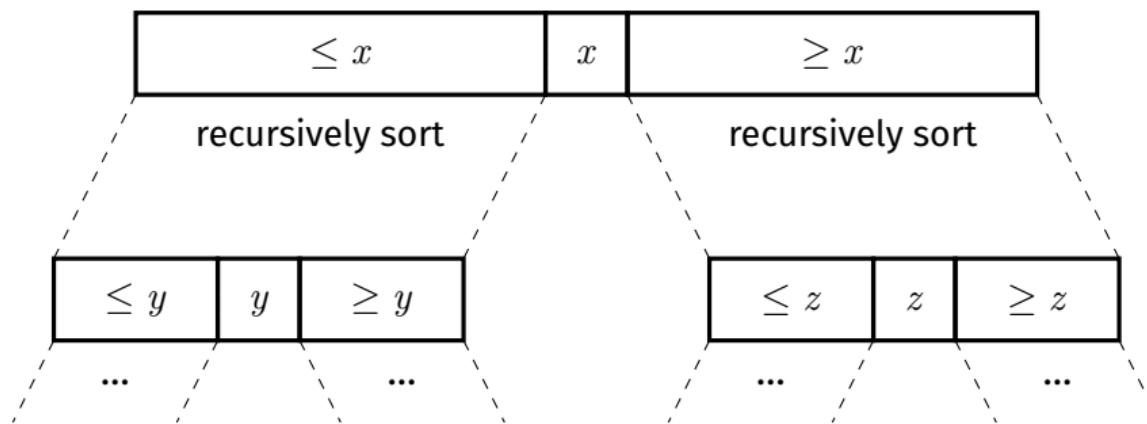

```
int partition(Item items[], int lo, int hi) {
    Item pivot = items[lo];

    int l = lo + 1;
    int r = hi;
    while (l < r) {
        while (l < r && le(items[l], pivot)) l++;
        while (l < r && ge(items[r], pivot)) r--;
        if (l == r) break;
        swap(items, l, r);
    }

    if (lt(pivot, items[l])) l--;
    swap(items, lo, l);
    return l;
}
```

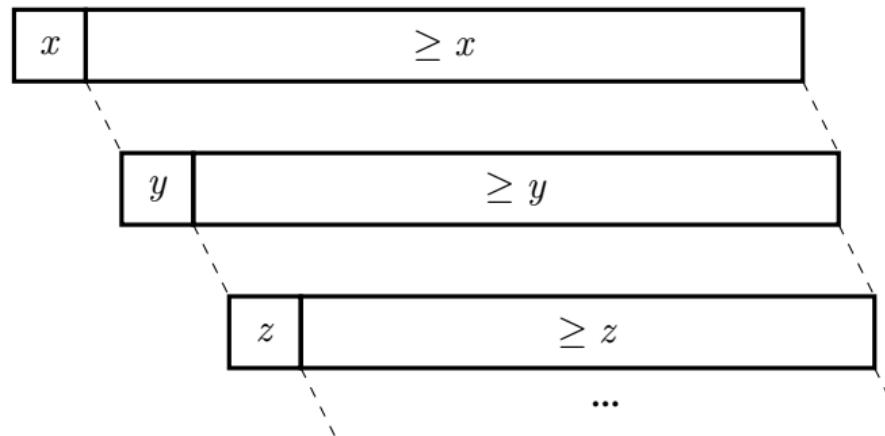

Best case:  $O(n \log n)$

- Choice of pivot gives two equal-sized partitions
- Same happens at every recursive call
  - Resulting in  $\log_2 n$  recursive levels
- Each “level” requires approximately  $n$  comparisons

Worst case:  $O(n^2)$

- Always choose lowest/highest value for pivot
  - Resulting in partitions of size 0 and  $n - 1$
  - Resulting in  $n$  recursive levels
- Each “level” requires one less comparison than the level above

Average case:  $O(n \log n)$

- If array is randomly ordered, chance of repeatedly choosing a bad pivot is very low
- Can also show empirically by generating random sequences and sorting them

**Unstable**

Due to long-range swaps

**Non-adaptive**

$O(n \log n)$  average case, sorted input does not improve this

**In-place**

Partitioning is done in-place

Stack depth is  $O(n)$  worst-case,  $O(\log n)$  average

Choice of pivot can have a significant effect:

- Ideal pivot is the median value
- Always choosing largest/smallest  $\Rightarrow$  worst case

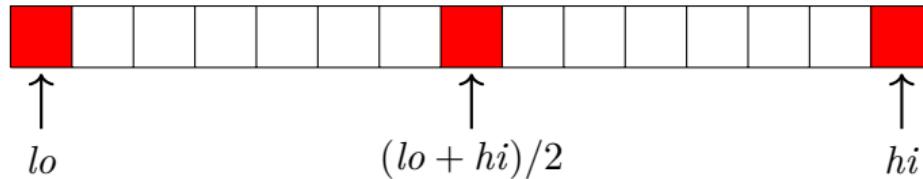

Therefore, always picking the first or last element as pivot is not a good idea:

- Existing order is a worst case
- Existing reverse order is a worst case
- Will result in partitions of size  $n - 1$  and 0
- This pivot selection strategy is called naïve quick sort

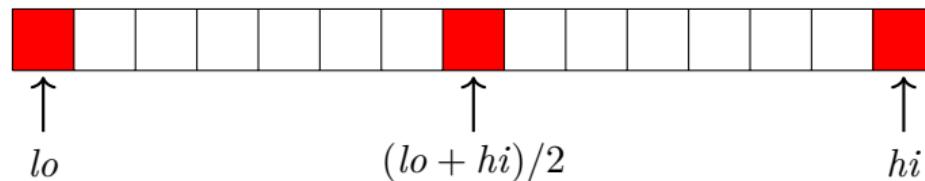

# Quick Sort with Median-of-Three Partitioning

Pick three values: left-most, middle, right-most.  
Pick the median of these three values as our pivot.

Ordered data is no longer a worst-case scenario.  
In general, doesn't eliminate the worst-case ...  
... but makes it much less likely.

## Quick Sort with Median-of-Three Partitioning

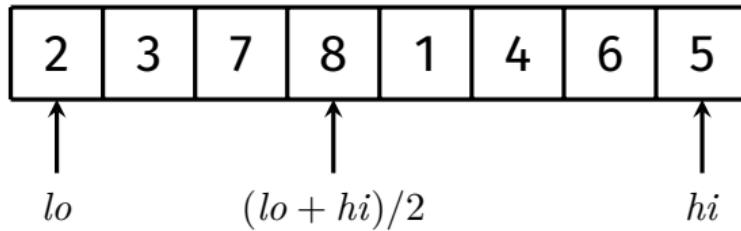

- ① Sort  $a[lo], a[(lo + hi)/2], a[hi]$ , such that  $a[(lo + hi)/2] \leq a[lo] \leq a[hi]$
- ② Partition on  $a[lo]$  to  $a[hi]$

## Quick Sort with Median-of-Three Partitioning

Example

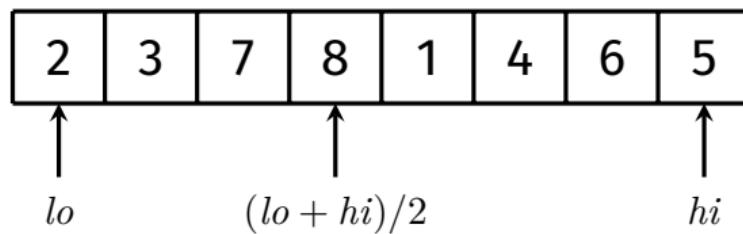

Which element is selected as the pivot?

## Quick Sort with Median-of-Three Partitioning

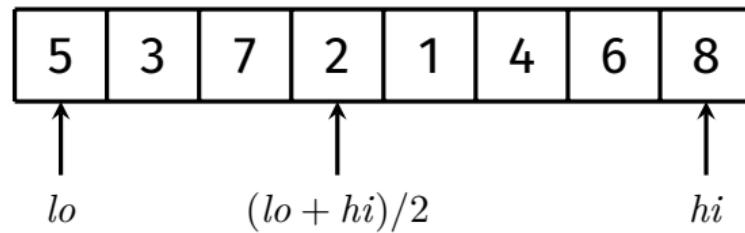

Example

Answer: 5

## Quick Sort with Median-of-Three Partitioning

Example

## Quick Sort with Median-of-Three Partitioning

C Implementation

```
void medianOfThreeQuickSort(Item items[], int lo, int hi) {  
    if (lo >= hi) return;  
    medianOfThree(items, lo, hi);  
    int pivotIndex = partition(items, lo, hi);  
    medianOfThreeQuickSort(items, lo, pivotIndex - 1);  
    medianOfThreeQuickSort(items, pivotIndex + 1, hi);  
}  
  
void medianOfThree(Item a[], int lo, int hi) {  
    int mid = (lo + hi) / 2;  
    if (gt(a[mid], a[lo])) swap(a, mid, lo);  
    if (gt(a[lo], a[hi])) swap(a, lo, hi);  
    if (gt(a[mid], a[lo])) swap(a, mid, lo);  
    // now, we have a[mid] <= a[lo] <= a[hi]  
}
```

# Quick Sort with Randomised Partitioning

Idea: Pick a random value for the pivot

This makes it *nearly* impossible to systematically generate inputs that would lead to  $O(n^2)$  performance

```
void randomisedQuickSort(Item items[], int lo, int hi) {  
    if (lo >= hi) return;  
    swap(items, lo, randint(lo, hi));  
    int pivotIndex = partition(items, lo, hi);  
    randomisedQuickSort(items, lo, pivotIndex - 1);  
    randomisedQuickSort(items, pivotIndex + 1, hi);  
}  
  
int randint(int lo, int hi) {  
    int i = rand() % (hi - lo + 1);  
    return lo + i;  
}
```

Note: `rand()` is a pseudo-random number generator provided by `<stdlib.h>`.  
The generator should be initialised with `srand()`.

For small sequences (when  $n < 5$ , say),  
quick sort is **expensive**  
because of the recursion overhead.

Solution: Handle small partitions with insertion sort

```
#define THRESHOLD 5

void quickSort(Item items[], int lo, int hi) {
    if (hi - lo < THRESHOLD) {
        insertionSort(items, lo, hi);
        return;
    }

    medianOfThree(items, lo, hi);
    int pivotIndex = partition(items, lo, hi);
    quickSort(items, lo, pivotIndex - 1);
    quickSort(items, pivotIndex + 1, hi);
}
```

```
#define THRESHOLD 5

void quickSort(Item items[], int lo, int hi) {
    doQuickSort(items, lo, hi);
    insertionSort(items, lo, hi);
}

void doQuickSort(Item items[], int lo, int hi) {
    if (hi - lo < THRESHOLD) return;

    medianOfThree(items, lo, hi);
    int pivotIndex = partition(items, lo, hi);
    doQuickSort(items, lo, pivotIndex - 1);
    doQuickSort(items, pivotIndex + 1, hi);
}
```

It is possible to quick sort a linked list:

- ① Pick first element as pivot
  - Note that this means ordered data is a worst case again
  - Instead, can use median-of-three or random pivot
- ② Create two empty linked lists  $A$  and  $B$
- ③ For each element in original list (excluding pivot):
  - If element is less than (or equal to) pivot, add it to  $A$
  - If element is greater than pivot, add it to  $B$
- ④ Recursively sort  $A$  and  $B$
- ⑤ Form sorted linked list using sorted  $A$ , the pivot, and then sorted  $B$

Design of modern CPUs mean,  
for sorting arrays in RAM  
quick sort *generally* outperforms merge sort.

Quick sort is more ‘cache friendly’: good locality of access on arrays.

On the other hand, merge sort is readily stable, readily parallel, a good choice for sorting linked lists

## Summary of Divide-and-Conquer Sorts

	Time complexity			Properties	
	Best	Average	Worst	Stable	Adaptive
Merge sort	$O(n \log n)$	$O(n \log n)$	$O(n \log n)$	Yes	No
Quick sort	$O(n \log n)$	$O(n \log n)$	$O(n^2)$	No	No
