- Sometimes when you're doing DP your solution will be too slow but your recurrence is very structured.
- You've seen this before with ranges and range trees.
- This lecture will show a few more cases of structured recurrences where there are well known techniques for speeding them up.
- Again, this does not help if your state space is too large.
 This should not really change your overall approach to DP but you should keep an eye out for recurrences that can be sped up.

- Suppose you are doing a 1D DP, calculating dp[1..N] in order of increasing i.
- Suppose you also have:
 - an array m[1..N] in decreasing order think of these as gradients, and
 - an array p[1..N] think of these as the positions of the points for which you are calculating $dp[\cdot]$.
- ullet You have some base case value dp[0] and the recurrence is

$$dp[i] = \min_{j < i} (dp[j] + m[j] \cdot p[i]).$$

DP Optimization

Take a look at the recurrence

$$dp[i] = \min_{j < i} (dp[j] + m[j] \cdot p[i]).$$

- Hopefully you see an $O(N^2)$ solution.
- What do those terms in the min look like?
- Equations for lines with dp[j] as the y-intercept and m[j] as the slope.

DP Optimization

Convex Hull Trick

Construction Application

Example

Conquer Optimization

Divide and Conquer Framework

Proving monotonicity of opt

Vrapping Up

Recurrence:

$$dp[i] = \min_{j < i} (dp[j] + m[j] \cdot p[i])$$

Suppose so far we have

$$dp[0] = -2,$$
 $m[0] = 2$
 $dp[1] = -1,$ $m[1] = 1$
 $dp[2] = 5,$ $m[2] = -1$

and we want to calculate dp[3] (leave p[3] unfixed for now).

Conquer Optimizatio

Divide and Conquer Framework

Proving monotonicity of opt

Modification

Vrapping Up

Recurrence:

$$dp[i] = \min_{j < i} (dp[j] + m[j] \cdot p[i])$$

 Then dp[3] is the minimum of a set of lines at the x-coordinate p[3], where our lines are:

$$y = m[0]x + dp[0] = 2x - 2$$

 $y = m[1]x + dp[1] = x - 1$
 $y = m[2]x + dp[2] = -x + 5$

• So far we have calculated each value dp[i] in O(N), by iterating through all of these lines. We will see how to speed this up.

- To speed up this recurrence, we will build a data structure that exactly supports the operations we need.
- It will export 2 methods:
 - void add(int m, int b): Add a line ℓ = m · x + b.
 Requirement: m is strictly less than the gradient of all lines in the data structure already.
 - int query(q): Over all lines $\{\ell_i = m_i x + b_i\}$ that we have added so far, return

$$\min_{i}(m_i\cdot q+b_i).$$

- We will have add run in O(1) amortized and query run in $O(\log n)$ where n is the number of lines added so far.
- Afterwards we will apply this data struture as a black box to some DP problems.

- Key Observation: This is the upper convex hull of the areas below the lines.
 - This means each line is optimal for a contiguous range of x (possibly empty) and as we move left to right, the gradient of the optimal line never increases.
- Our goal is to maintain the convex hull by maintaining the set of line segments that the convex hull is made out of.
- We will say a line ℓ is dominant at x-coordinate x if it is the line that forms the convex hull at x, i.e. the line that gives the minimum in the equation

$$query(q) = \min_{i} (m_i \cdot q + b_i).$$

- For this, it suffices to store the lines that make up the convex hull in left to right order, i.e. in decreasing order of gradient.
- **Note:** Importantly, this does not contain all the lines. It omits any line that is never in the upper convex hull.
- Given this data, we can calculate the range of x at which each line ℓ is dominant.
- The segment is the range between the intersection of ℓ with the line before it and the line after it in the convex hull.
- We keep the lines in a vector.

Conquer Optimization Divide and Conquer Framework

Proving monotonicity of opt

Modification

Wranning Un

- Our aim is to find the line that is dominant at x = q.
- Suppose our lines are ordered in decreasing gradient order. Then recall the range at which line ℓ_i is dominant is

[intersect(
$$\ell_{i-1}, \ell_i$$
), intersect(ℓ_i, ℓ_{i+1})]

where for i=0, the left term is $-\infty$ and for the last line, the right term is $+\infty$.

 So to find the *i* for which the segment contains *q*, it suffices to find the minimum *i* such that

$$intersect(\ell_i, \ell_{i+1}) \geq q$$
.

- One common case is when we make queries in non-decreasing order.
- Formally, say our code calls query with

$$query(q_1), query(q_2), \dots, query(q_Q).$$

Then
$$q_1 \leq q_2 \leq \ldots \leq q_Q$$
.

- In this case, the index of the dominant line for each q_i only increases.
- So we keep track of the index of the dominant line.
 Whenever we query, we check if the current dominant line is still the dominant line for the new query point.

DP

. Convex Hull

Construction
Application
Examples

Divide and Conquer Optimization Divide and Conquer Framework

...

 If cp is the current dominant line, this amounts to checking if

$$p[i] \leq intersect(cht[cp], cht[cp + 1]).$$

- While this does not hold, increase cp.
- The above had an omission there is a special case. Since the number of lines in the convex hull can decrease, cp may be out of bounds. To fix this, after each update we just need to update cp to point to the last line if it is out of bounds.
- If you want to rigorously check this, the invariant you are maintaining is

$$intersect(cht[cp-1], cht[cp]) \le p[i].$$

Conquer
Optimization
Divide and

Proving monotonicity of opt

Modification

Wranning IIn

- Not hard to adjust for gradients non-increasing (instead of decreasing) - just one extra special case.
- Can also have no conditions on the gradients. We still keep lines in sorted gradient order.
- However, we now need to keep lines in a set since insertions are arbitrary.
- Not that common mostly because it is tedious to get right.
- Alternatively we can also use a "Li Chao tree".

DP Optimizations

Convex Hull Trick

Construction
Application
Examples

Divide and Conquer Optimization Divide and Conquer Framework Proving monotonicity

Wrapping Up

- Another useful modification is when everything (gradients and query points) is in integers.
- Currently we use doubles to compute the intersection points. This gives us the precise ranges at which we dominate (up to precision errors)
 [intersect(cht[i-1], cht[i]), intersect(cht[i], cht[i+1])].
- Doubles are not precise though even for the range of a long long. Usually not problematic for competitions since numbers generally only go up to 10^9 but you have to keep it in mind if you need to query higher.
- If we only care about integer coordinates of x then we can round these down and work entirely in integers:

```
(\lfloor \mathsf{intersect}(\mathit{cht}[\mathit{i}-1], \mathit{cht}[\mathit{i}]) \rfloor, \lfloor \mathsf{intersect}(\mathit{cht}[\mathit{i}], \mathit{cht}[\mathit{i}+1]) \rfloor]
```

monotonicity of opt Modification

Mrapping IIp

- Just be careful. If you want to do this, make sure it is clear to you why the above is exclusive-inclusive.
- In integers, whether your inequalities are strict or not actually matters. When you compare with an intersection point, mentally check if it agrees with the above ranges.
- If we only care about *positive* integers, we can omit the floor and just use regular integer division.
- But if you care about negatives, note that integer division isn't floor; it rounds towards 0.

    l.m = m[0];
    l.b = dp[0];
    add(1);

    for (int i = 1; i < N; i++) {
        dp[i] = query(p[i]);
        line l;
        l.m = m[i];
        l.b = dp[i];
        add(1);
    }
    return 0;
}</pre>
```

DP Optimizations

Convex Hull Trick

Construction Application

Examples

Conquer Optimization

Divide and Conquer Framework

Proving monotonicit of opt

Modification

Wranning IIn

- Complexity? $O(N \log N)$.
- This is a significant improvement from $O(N^2)$!
- Note, we could even get O(N) if our p[i] are non-decreasing.

Key Takeaways

DPs with recurrences in the form

$$dp[i] = \min_{j < i} (dp[j] + m[j] \cdot p[i])$$

can be done in $O(N \log N)$.

- Use a data structure for CHT which supports:
 - void add(int m, int b): Add a line l = m·x + b.
 Requirement: m is strictly less than the gradient of all lines in the data structure already.
 - int query(q): Over all lines $\{\ell_i = m_i \cdot x + b_i\}$ that we have added so far, return

$$\min_{i} (m_i \cdot q + b_i)$$
.

 You can treat this data structure as a black box. However it is good to at least know how to tweak it using the 2 knobs mentioned above.

DP Optimization

Convex Hull Trick

Application

Divide and Conquer Optimization

Divide and Conquer Framework Proving

monotonicity of opt

In practice, the difficulty of CHT comes from:

- Recognizing that it is useful.
 - Often you just have to write out the recurrences.
 - Be suspect whenever the recurrence is given by a formula.
- Figuring out how to calculate the gradients and y-intercepts.
 - You will often have to juggle around terms in the recurrence to make it work.
 - This comes mostly with practice.
- Essentially, the recurrence

$$dp[i] = \min_{j < i} (dp[j] + m[j] \cdot p[i])$$

tells us that we need the gradient to be a function of only j and the query point to be a function of only i.

Recurrence:

$$dp[j] = \min_{i < j} (dp[i-1] + C + x[i]^2 + x[j]^2 - 2 \cdot x[i] \cdot x[j]).$$

 If you recall, we were earlier looking at recurrences of the form

$$\min_{i < j} (dp[i] + m[i] \cdot p[j]).$$

- What should m[i] and p[j] be?
- We should have m[i] = -2x[i] and p[j] = x[j], since we need the gradient to be determined by i and the query point by j.
- Note that our gradients are decreasing, which is required for CHT!

monotonicit
of opt

.. . ..

Recurrence:

$$dp[j] = \min_{i < j} \left(dp[i-1] + C + x[i]^2 + x[j]^2 - 2 \cdot x[i] \cdot x[j] \right).$$

- We also need to modify the y-intercept of the line; it isn't just dp[i] anymore. What should it be?
- **Key:** It needs to include all terms dependent on *i*. So it needs to include dp[i-1] and $x[i]^2$. **Why?**
- But it can't include $x[j]^2$ for obvious reasons. So we should add the $x[j]^2$ part when we calculate dp[j].
- You can choose whether to add C when you calculate dp[j] or instead add C to the y-intercept.

Examples

Recurrence:

$$dp[j] = \min_{i < j} (dp[i-1] + C + x[i]^2 + x[j]^2 - 2 \cdot x[i] \cdot x[j]).$$

So for each i we will add a line with y-intercept

$$dp[i-1] + x[i]^2$$

and gradient -2x[i].

• To calculate dp[j], we query our CHT with point x[j]. Define r := query(x[i]). Then

$$dp[j] = r + C + x[j]^2.$$

- Complexity? We note our query points p[j] = x[j] are increasing in j, so we can use the O(1) amortized CHT. Then the complexity is just O(N).
- Since our query points are integers, we can also use the version of CHT with no doubles.
- Using just integer division doesn't change the complexity but in practice is a large speed up (I get a 3 times speedup locally).

monotonicity of opt Modification

Vrapping Up

This is how many CHT problems go.

- First you come up with a normal DP that is too slow. This step is the same as in the previous DP lecture.
- Then you note the recurrence is a nice formula. Write it out.
- Now, split up the recurrence as in this example.
 Figure out which part corresponds to the slope and query point and how to split up the constant into the y-intercept and the part added when you calculate dp[j].
- Usually this is just breaking up the terms based on if they depend on j or on i.

• Problem Statement:

You have N soldiers in a line, the ith of which has effectiveness x_i .

You want to partition the soldiers into squadrons. Each squadron consists of a subsegment of *contiguous* soldiers. Say these soldiers have total effectiveness S. Then the effectiveness of the squadron is $AS^2 + C$ where A < 0 and C are given constants.

Maximize the sum of the effectiveness of the squadrons.

• Input Format:

First line contains three integers, N, A, C.

$$1 \le N \le 10^6, -5 \le A \le -1, |C| \le 10^4.$$

Next line contains N integers, the effectiveness of the soldiers in order.

Each effectiveness satisfies $1 \le x_i \le 100$.

Examples

Optimization

Divide and

Proving monotonicity of opt

Wranning Un

- Useful trick: We want to clean up the sum in the square.
 It is often easier to work with cumulative arrays than sums.
 - Define S[N] to be the cumulative sum, $S[i] := (x_1 + ... + x_i).$
 - Then let's rewrite the recurrence.

$$dp[j] = \max_{i < j} (dp[i-1] + C + A(S[j] - S[i-1])^{2})$$

$$= \max_{i < j} (dp[i-1] + C + A \cdot S[i-1]^{2} + A \cdot S[j]^{2}$$

$$-2A \cdot S[i-1] \cdot S[j])$$

This gives a much cleaner separation between terms in i and terms in j.

DP Optimization

Convex Hull
Trick
Construction
Application

Examples

Divide and Conquer Optimization Divide and Conquer Framework Proving monotonicit $b[i] + m[i] \times p[j]$ form. Let us do the latter part first. • What is m[i]? $-2A \cdot S[i-1]$. So p[j] = S[j].

Again, main question is to convert this into

- What is m[i]? $-2A \cdot S[i-1]$. So p[j] = S[j]. Gradient is increasing (since A is negative), which is correct for maximization problems.
- How about the constant? Which parts form b[i], and which parts should we add directly to dp[j]?
- Again, we need b[i] to include $dp[i-1] + A \cdot S[i-1]^2$. This time around we will also include C in b[i].

Recurrence:

$$dp[j] = \max_{i < j} (dp[i-1] + C + A \cdot S[i-1]^{2} + A \cdot S[j]^{2}$$

$$(-2A \cdot S[i-1] \cdot S[j])$$

• So for *i* we will add a line with *y*-intercept

$$dp[i-1] + A \cdot S[i-1]^2 + C$$

and gradient $-2A \cdot S[i-1]$.

• To calculate dp[j], we query our CHT with point S[j]. Define r := query(S[j]). Then

$$dp[j] = r + A \cdot S[j]^2.$$

/* Insert CHT code here: You can use the version with only
 * positive integer queries and non-decreasing queries */
void add(line 1);
long long query(long long x);
const int MAXN = 1000000:
int N;
long long a, c;
long long S[MAXN+1];
long long dp[MAXN+1];
int main() {
    scanf("%d", &N);
    scanf("%11d %11d %11d", &a, &c);
   for (int i = 1: i \le N: i++) {
        long long x; scanf("%lld", &x);
        S[i] = S[i-1] + x;
    for (int i = 1: i \le N: i++) {
       line 1;
       1.m = -2*a*S[i-1]:
        1.b = dp[i-1] + a*S[i-1]*S[i-1] + c;
        add(1);
        dp[i] = query(S[i]) + a*S[i]*S[i];
    printf("%lld\n", dp[N]);
    return 0;
```

- This time around we want to maximize the value.
 However, our code for CHT works for both min (with decreasing gradients) and max (with increasing gradients) without modification.
 - Complexity? We note our query points p[j] = S[j] are increasing in j, so we can use the O(1) amortized CHT. Then the complexity is just O(N).
- One should be a bit cautious here of overflows. Here S[i] can go up to 10^8 , but we take $S[i]^2$, and dp[i] can go up to around 10^{13} . This is okay with long longs.
- Our y-intercepts go up to around 10¹⁶, so we're going to lose precision if we use double for our intercepts. This seems to be OK since our query points only go up to 10⁸ (it gets AC) but it's at least a concern.

- Hope you can see an $O(N^2K)$ DP.
- Our state will be dp[k][i], the minimum noisiness to partition the first i kids into k groups.
- We will proceed in increasing *k* and increasing *i* order.
- Recurrence is

$$dp[k][i] = \min_{j < i} (dp[k-1][j] + (s_{j+1} + \ldots + s_i)^2).$$

- Naively this recurrence is $O(N^2)$, there are O(N) values of j and the sum takes O(N) to calculate. How do we speed up this recurrence to O(N)?
- Cumulative sum!

Example Problem: Noisy Kids

Divide and

Conquer Optimization

```
#include <bits/stdc++.h>
using namespace std:
const long long INF = 1e17:
const int MAXN = 10000:
const int MAXK = 100;
int N, K;
// 1-indexed. S[i] = sum(s_1 + ... + s_i)
long long S[MAXN+1];
long long dp[MAXK+1][MAXN+1];
int main() {
    scanf("%d %d", &N, &K);
    for (int i = 1; i \le N; i++) {
        long long s: scanf("%lld", &s):
        S[i] = S[i-1] + s;
    for (int i = 1; i \le N; i++) dp[0][i] = INF;
    for (int k = 1; k \le K; k++) {
        for (int j = 1; j \le N; j++) {
            dp[k][j] = INF;
            for (int t = 0; t < j; t++) {
                dp[k][i] = min(dp[k][i],
                         dp[k-1][t] + (S[j]-S[t])*(S[j]-S[t]);
            }
        }
    printf("%11d\n", dp[K][N]);
    return 0;
```

Example Problem: Noisy Kids

Let us take a look at the recurrence again:

$$dp[k][i] = \min_{j < i} \left(dp[k-1][j] + (s_{j+1} + \ldots + s_i)^2 \right).$$

- Let opt[k][i] be the argmin, i.e. the value of j at which the minimum is attained in the above recurrence. If there's several, pick any.
- Key Claim:

$$opt[k][i] \leq opt[k][i+1]$$

- Proof later. Intuitively, one expects increasing i to move our groups to the right. If opt[k][i+1] < opt[k][i] then the kth group for i+1 encompasses the kth group for i. This seems wrong because the cost of squaring increases quicker the larger the group gets.
- More formally, the key is x^2 is *convex*.

Construction Application

Example:

Conquer Optimization Divide and Conquer Framework

Proving monotonicity of opt Modifications

- For concreteness, let $Cost(i, j) := (S[j] S[i])^2$.
- I claim Cost(i, j) satisfies the following key feature: if a < b < c < d, then

$$\mathsf{Cost}(a,d) - \mathsf{Cost}(b,d) \ge \mathsf{Cost}(a,c) - \mathsf{Cost}(b,c).$$

- What does this say? Suppose we started by looking at the ranges [b, c] and [b, d] and we define A := Cost(b, c) and B := Cost(b, d).
- Then it says that adding an extra item to the interval [b, d] increases the cost more than adding the same item to the interval [b, c].

 But when our function is squaring, this key feature is immediately true. It just says that

$$(B+c)^2 - B^2 \ge (A+c)^2 - A^2$$

if $B > A \ge 0$.

• This follows from x^2 being convex (its derivative is an increasing function).

Framework

Proving monotonicity of opt

Modification

Now, let Cost be any function that satisfies

$$\mathsf{Cost}(a,d) - \mathsf{Cost}(b,d) \ge \mathsf{Cost}(a,c) - \mathsf{Cost}(b,c)$$

for all a < b < c < d.

- To prove opt[k][i] is increasing in i, we proceed with the standard swapping argument.
- Suppose for a contradiction that opt[k][i+1] < opt[k][i].

• Then on the one hand by definition of $o_{k,i+1}$:

$$dp[k-1][o_{k,i+1}] + Cost(o_{k,i+1}, i+1) < dp[k-1][o_{k,i}] + Cost(o_{k,i}, i+1),$$

or equivalently:

$$Cost(o_{k,i+1}, i+1) - Cost(o_{k,i}, i+1)$$

 $< dp[k-1][o_{k,i}] - dp[k-1][o_{k,i+1}].$

• But the opposite situation holds for $o_{k,i}$:

$$dp[k-1][o_{k,i}] + Cost(o_{k,i}, i)$$

 $< dp[k-1][o_{k,i+1}] + Cost(o_{k,i+1}, i),$

or equivalently:

$$dp[k-1][o_{k,i}] - dp[k-1][o_{k,i+1}]$$

< $Cost(o_{k,i+1}, i) - Cost(o_{k,i}, i)$.

• Composing these two inequalities, we get

$$\begin{aligned} &\mathsf{Cost}(o_{k,i+1},i+1) - \mathsf{Cost}(o_{k,i},i+1) \\ &< \mathsf{Cost}(o_{k,i+1},i) - \mathsf{Cost}(o_{k,i},i) \end{aligned}$$

exactly contradicting the desired inequality on Cost, since

$$o_{k,i+1} < o_{k,i} < i < i+1.$$

DP

Optimization

Convex Hul Trick

Application
Examples

Divide and Conquer Optimization Divide and Conquer Framework

Proving monotonicity of opt Modifications

Wrapping Up

This inequality

$$\mathsf{Cost}(a,d) - \mathsf{Cost}(b,d) \ge \mathsf{Cost}(a,c) - \mathsf{Cost}(b,c)$$

for all a < b < c < d is called the quadrangle inequality.

- You should think of it as saying the larger your segment already is, the more costly it is to put items into it.
- So intuitively, one might expect this to imply monotonicity of opt, since moving the right endpoint from i to i+1 should disincentivise the last segment growing any larger to the left.
- This is what the above proof showed. Hence, satisfying the quadrangle inequality is sufficient for opt to be monotonic, allowing us to apply D&C Optimisation.

Examples of good cost functions

Some examples:

Our example involved

$$Cost(i,j) = F(s_{i+1} + \ldots + s_j)$$

where $F(x) = x^2$. If all our $\{s_i\}$ are positive then Cost satisfies the quadrangle inequality whenever F is convex. So $F(x) = x^3, x\sqrt{x}, x\log x$ all work.

Also a lot of CHT, i.e.

$$Cost(i,j) = b_i + m_i \cdot p_j$$

where the m_i are non-increasing and the p_j are non-decreasing. Conversely, a decent number of D&C problems can be solved with CHT after clever rewriting.

• By induction, it suffices to prove it for one step:

$$\mathsf{Cost}(b-1,c+1) - \mathsf{Cost}(b,c+1) \ge \mathsf{Cost}(b-1,c) - \mathsf{Cost}(b,c).$$

- Often Cost(i, j) is defined as some function operating on the multiset of $\{s_i, s_{i+1}, \ldots, s_j\}$. For these, proving a single step is often easy.
- For example,

$$Cost(i,j) = |\{(a,b) \mid s_a + s_b = 0 \land a, b \in [i,j]\}|.$$

Key Takeaways

ND

Convex Hull Trick Construction

Exampl

Divide and Conquer Optimization Divide and Conquer Framework Proving

Proving monotonicity of opt Modifications

Wrapping Up

Key Takeaways:

- To show opt is monotone, we almost always instead show that Cost satisfies the quadrangle inequality.
- You don't need to know why Cost satisfying the quadrangle inequality implies monotonicity of opt. But it is worth knowing roughly how to check the inequality holds.
- Intuitively, it just says the larger a range already is, the more Cost increases more upon adding another item.
- Many Cost functions satisfy the quadrangle inequality, in particular convex functions applied to the sum of the range.
- If Cost satisfies the quadrangle inequality or we suspect it does, then we can apply the earlier Divide and Conquer framework directly just by modifying the Cost function.

DP Ontimization

Trick

Application

Divide and Conquer Optimization

Framework
Proving

of opt

Modifications

Wrapping Up

 For maximisation problems, we want the opposite quadrangle inequality

$$Cost(a, d) - Cost(b, d) \le Cost(a, c) - Cost(b, c),$$

that is, it is harder to increase the cost of larger segments.

- Examples include concave functions such as $F(x) := \sqrt{x}$ and $F(x) = \log x$.
- Again, it suffices to prove it for a single step.
- Often the annoying part is calculating Cost(i, j) quickly.
- For example, consider

$$Cost(i, j) = |\{(i, j) | s_i + s_j = 0\}|.$$

For D&C it is too slow to calculate this in O(j-i).

Wranning IIn

• The quadrangle inequality further gives that

$$opt[k-1][i] \leq opt[k][i] \leq opt[k][i+1]$$

Using this and doing the DP in increasing k order, then decreasing i order, gives a running time of O((N+K)N). This is sometimes called "Knuth's Optimisation". (though I feel this term is overloaded)

Arapping Hp

Problem Statement:

There are N mines on a river, of which the ith is at position X_i and produces W_i units of coal. To collect coal, K facilities will be built on the river. The river only flows downstream so coal from position i can be delivered to position j iff j > i. To deliver w units of coal from position X to Y costs $w \cdot (Y - X)$ units of fuel. If we optimally position the facilities, what is the minimum amount of fuel necessary to collect all the coal?

- Wrapping Up

- As always, start simple. What order to process in and what state?
- The standard ones for 2D DP. State is dp[k][i], the minimum cost to collect coal exactly from the first i mines using k facilities.
- Order is increasing k then increasing i.
 Increasing i then k works too.
- \bullet Recurrence? Has to be something about building facilities.
- Easy Observation: We should only build facilities at mines.
- By definition, in the state dp[k][i], we must build a facility at mine i.
- So what is left to choose? Where the previous facility was built.

Recurrence:

$$dp[k][i] = \min_{j < i} \left(dp[k-1][j] + \mathsf{Cost}(j,i) \right)$$

What is Cost(j, i) here? (in words)

- It is the total cost to deliver coal from mines $j+1, \ldots, i$ to a facility at mine i.
- Formula is

$$\sum_{t=j+1}^{i} W_t \cdot (X_i - X_t).$$

- Exercise: Make this run in $O(N^2K)$ (Hint: Either rewrite the equation or do a backwards sweep to calculate the above min).
- $O(N^2K) \approx 8 \times 10^9$. Too slow (at least without extreme micro optimization).

Modifications

- How to speed this up? Note this is a standard 2D DP where we are making a choice per state, but making this choice is introducing an O(N) cost. And we are blowing out due to this O(N) cost, not the state space.
 - So we should look at whether this choice has a nice monotone structure, i.e. is opt[k][i] ≤ opt[k][i+1]?
 - To check this, we should check the quadrangle inequality, or the one step version

$$\mathsf{Cost}(b-1,c+1) - \mathsf{Cost}(b,c+1) \ge \mathsf{Cost}(b-1,c) - \mathsf{Cost}(b,c).$$

- Important: What does your intuition tell you?
- My intuition tells me this seems likely.
 Adding another mine to a larger segment should incur more cost, compared to adding it to a smaller segment. In the former, the coal will have to be shipped further.

Modifications

We can also give a quick proof that the inequality

$$\mathsf{Cost}(b-1,c+1) - \mathsf{Cost}(b,c+1) \ge \mathsf{Cost}(b-1,c) - \mathsf{Cost}(b,c)$$

does indeed hold true.

Recall that

$$Cost(j, i) := \sum_{t=j+1}^{i} W_t \cdot (X_i - X_t).$$

- Most terms of the inequality cancel. What remains on the LHS is just $W_b \cdot (X[c+1] X[b])$, while RHS is just $W_b \cdot (X[c] X[b])$.
- Therefore the quadrangle inequality is satisfied and we can apply D&C optimization.

• The final ingredient is to calculate

$$Cost(j, i) := \sum_{t=i+1}^{i} W_t \cdot (X_i - X_t)$$

in constant time.

- The difficulty is that X_i varies, so we can't precompute this.
- Standard trick: rewrite this to isolate out the X_i part:

$$\mathsf{Cost}(j,i) := \left(\sum_{t=j+1}^i W_t\right) X_i - \left(\sum_{t=j+1}^i W_t X_t\right).$$

- How do we calculate this in O(1) now?
- Cumulative sums over the array W[N] and the array $\{W_tX_t\}_{t=1}^N$.

- Complexity? $O(NK \log N) \approx 4.4 \times 10^7$. Likely fine for a second on a relatively modern machine.
- Common in many problems of this kind.
 - Start with the obvious DP but the recurrence is too slow.
 - Look at the structure there. Since you are making choices, check if these choices might be monotone.
 You want your intuition to play a strong role here.
 - To apply D&C, want Cost to be around O(1) amortized.
 For simple examples, this usually just involves rewriting the equation until you can apply basic data structures.
 For more complicated examples, you may need to be more careful with how you persist state in your D&C.
- Aside: with some rewriting, not hard to do this with CHT either.
